"*To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

THURSDAY, MAY 4, 1893.

AN AMERICAN TEXT-BOOK OF PHYSICS.

Physics, Advanced Course. By George F. Barker, Professor of Physics in the University of Pennsylvania. Pp. 902. (London: Macmillan and Co., 1892.)

THE days are nearly over when a text-book of Physics in one volume is any longer a possibility. The attempt to compress so great a mass of knowledge into small compass seems necessarily to involve the omission of anything like the full elementary explanation required by junior students, as well as the more advanced discussion suitable to seniors; it also appears necessary to curtail any approach to a mathematical investigation, and to dispense with the details of experimental appliances.

With so much omitted it may surprise those who do not know what a vast region is now cultivated under the name Physics, that there is enough left to fill a bulky volume. But there is, and this volume contains it, viz. the quiet and systematic rehearsal of the broad facts of the subject, a statement free from rhetoric and from effort, a statement which flows placidly on in a peaceful and easy flow.

The absence of friction renders the book hardly suitable for a beginner, especially one without a teacher; he could hardly manage to grip the facts as they passed him. But after a serious course of lectures, after a disjointed struggle with difficulties in this or that department, it would be a pleasant relief to a student to have a book like this put into his hands as a kind of glorified note-book, that he may leisurely revise the whole in a corrected and simple form. If a third year student is able to read this book feeling that it continually excites in him recollections of the more detailed treatment he has elsewhere acquired, he may be satisfied that he knows a good deal of Physics; if, on the other hand, he comes across pages where the matter is new and where he has any difficulty in apprehending what is said, he may feel assured that here there is something desirable for him to attend to and learn from any of the more detailed and elaborate sources open to him.

That is how the book strikes me: as one eminently suited to assist a student's revision of the subject, so as to ensure that his knowledge may be free from glaring gaps; but not as a book that could be recommended for learning from. It would probably, as I have said, be difficult to learn from, but a still more fatal objection to its use by a solitary learner is the probability that its easy flow would convey an altogether erroneous impression of the difficulties that really bristle about the subject, and would lead to only a very superficial smattering, quite incommensurate with the vast amount of information which is summarised and made more or less palatable by this genial treatise.

Having thus indicated what seems to me the general usefulness of the book I proceed to indicate its contents. It begins with fundamental units and the laws of mechanics, together with a summary of the properties of matter. Then it proceeds to treat of Energy as belonging to various bodies; masses, molecules, and the ether. This is the classification definitely adopted throughout the book—it is a treatise on the forms of energy. "Mass physics, molecule physics, and æther-physics; and the fact is significant that to the last division of the subject it has been found necessary to devote more than half of the entire work." "Radiation is considered broadly, without any special reference to those wave-frequencies which excite vision and are ordinarily called light." Modern references abound, and the subjects dwelt on are those which at the present time are most exciting attention. "The author's aim has been to avoid making the book simply an encyclopædic collection of facts on the one hand, or too purely an abstract and theoretical discussion of physical theories on the other." "He has made free use of all the sources of information at his command. . . The names of those physicists to whom the science is most deeply indebted are given in connection with the subjects on which they have worked, and in order to bring the student into more intimate contact with these great minds, the laws or principles they have formulated have frequently been given in their own words."

This free quotation is characteristic of the book, and sometimes it could be wished that a chapter and verse reference for further following up had been given, instead of only the mere name. But, after all, such reference would have been fidgeting and out of harmony with the even tenor of the text, which is about as different as it can possibly be from the productions of German authors.

I do not myself think it a good plan to incorporate formulæ in the text, so that there is nothing for the eye to catch. Such a proceeding may be convenient to the printer, but it is only permissible when the expressions are very simple and easy ones. However, all those in this book are simple and easy ones, so possibly no student need feel any inconvenience.

So far as I have observed, the statements made are usually clear and correct. There are some few exceptions; for instance, the definition of self-induction on pp. 814, 815 is not satisfactory. On p. 858 the distance apart of points, between which unit difference of magnetic potential exists, is unnecessarily specified in the definition of Verdet's constant; but this is a slip made also in Everett's "Units," and is an easy one both to make and to correct.

The account of a volume-air-thermometer given on p. 295 can hardly pass muster; and indeed this and other meagre references to the work of Regnault may be taken as typical of the absence of even the outlines of those experimental details which one is accustomed to find in the writings of French authors.

But, as I said at the beginning, the attempt to compress all physics into one volume of reasonable size and good print can only be made if one is content to omit about 90 per cent. of what might be included. As a convenient summary of a course of lectures of a particular grade the book is probably about as good as can be expected, and it may be found useful for revision-work by students in this country.

OLIVER LODGE.

BABYLONIAN COSMOLOGY.

Die Kosmologie der Babylonier. Studien und Materialen von P. Jensen. (Strassburg.)

THE thick volume of five hundred and fifty pages of closely printed matter lying before us represents what was originally intended by its author to be the first part of an exhaustive treatise upon the mythology of the Babylonians in the widest sense of the term, but he was obliged to abandon the scheme after investigating the spiritual and religious views of the Babylonians which the cuneiform texts make known to us, because he was driven by facts to admit that any such attempt would, with our present information, be premature. Prof. Jensen has then contented himself with placing in the hands of his readers a series of facts and a collection of materials for making researches into the astronomical system of the Babylonians, together with the results which he deduces from them. He is fain to admit that the present state of the study of this subject is lamentable in the extreme; for those who have worked at it in times past, and even those who still profess themselves to be devoted to the science, link idea to idea without regard to natural sequence, and draw conclusions, and invent systems, and give themselves over to traditions rather than to the serious discussion of the facts and statements of the cuneiform texts. Other writers being naturally incapable of distinguishing what is certain from that which is not, and possessing neither the knowledge necessary to control the work of Assyriologists, nor the power to work independently, reproduce the statements given doubtfully by scholars, and send them among non-experts as incontrovertible facts, and thus it comes that the greater part of the work which is current under the name of "Babylonian Mythology" must be considered base coin only.

The earliest worker in the field of Babylonian Astronomy was the famous Dr. Hincks, who published the result of his investigations of some cuneiform texts in the British Museum in the Transactions of the Irish Academy in 1856. In 1862 Sir Henry Rawlinson, the "Father of Assyriology," discovered that most important document now universally known as the "Eponym Canon," in which an eclipse of the sun was mentioned. As Dr. Hincks overlooked the fact that the greater number of the texts which he regarded as astronomical were purely astrological, this discovery by Sir Henry Rawlinson of the notice of an astronomical event recorded by the Babylonians, the accuracy of which could be demonstrated by modern mathematical calculations, must be considered as the first step towards a scientific elucidation of Babylonian astronomy, and a proof that pure astronomical science already existed in the Euphrates Valley as early as B.C. 700. In 1871 the veteran Assyriologist, Jules Oppert, published in the *Journal Asiatique* the results of his study of some syllabaries, and other texts in which the Babylonian names of the planets and other stars were given, and three years later Prof. Sayce published a lengthy paper entitled "The Astronomy and the Astrology of the Babylonians," in the Transactions of the Society of Biblical Archæology, in which he reprinted, without making a new collation, most of the astrological texts published by Rawlinson in "Cuneiform Inscriptions of Western Asia," vol. iii., to which he added English translations. On the work of these two last-mentioned Assyriologists Prof. Jensen makes some strong comments.

Passing over smaller works by Schrader and Lotz we next strike firm ground in the excellent work by Drs. Epping and Strassmaier. The former is an astronomer of no mean skill and ability, and the latter is one of the greatest experts in modern cuneiform decipherment and is thoroughly skilled in working at the tablets at first hand. In the work entitled "Astronomisches aus Babylon," Freiburg i. B. 1889, these scholars published the texts from three tablets of lunar ephemerides for the years 188, 189, and 201 of the era of Seleucus, which began B.C. 312, together with a long astronomical commentary upon them and remarks upon Babylonian ephemerides of planets in general. From these texts it was evident that the Babylonians were accustomed to tabulate the heliacal rising and setting of the planets and of Sirius, and the opposition of the planets to the sun, and it was discovered that they had in the ecliptic a number of groups of stars, twelve of which correspond roughly in nomenclature and in position with the signs of the Zodiac. When this important publication appeared Prof. Jensen had for some years been independently working at the history of the origin of the Zodiac, and a large portion of his work now before us was already in type. A careful study of the new matter and of the theories based upon it by Drs. Epping and Strassmaier convinced him of the general correctness of the results of his own investigations, at which he had arrived by a method peculiarly his own, and by many new readings of the cuneiform names of planets and stars which he was enabled to explain satisfactorily he confirmed several identifications of stars which had been pointed out by Dr. Epping by the light of mathematical astronomy. It is but fair to say that at the outset some differences of opinion existed between these distinguished scholars, but already many of them have been adjusted, and the proof of the general accuracy of the work is therefore much stronger.

Prof. Jensen divides his book into two sections. In the first he treats of the "Universe and its Parts," and in the second of the "Creation and of the Formation of the World." Under the first heading, in a series of chapters, he discusses the sky and the heavenly bodies in it, special attention being paid to the consideration of the Zodiac, the earth, the Mountain of sunrise, the abodes of the blessed dead and of the damned, and of the Okeanos; and under the second he translates and explains the Babylonian texts referring to the Creation and to the Deluge. Many of Prof. Jensen's ideas are new, and will therefore fail to be accepted by those who prefer to follow traditions and their own views in preference to results obtained directly from the cuneiform texts which are, after all, our only trustworthy authority on Babylonian cosmology. He argues his propositions in a sober manner, and he arranges his facts with clearness; he gives proof or authority for every statement, and he assumes or takes for granted little or nothing. Prof. Jensen's book is a careful statement of all the important views of the Babylonians concerning the system of the heavens and the earth as recorded by the officia astronomers and astrologers attached to the library of Assurbanipal at Nineveh about B.C. 660. His work will command the respect and earn the gratitude of all true scholars, even of those who may disagree with him, and by reason of it the scientific astronomer of to-day with his telescope and spectroscope and instruments for stellar photography will respect his predecessors on the plains of Mesopotamia, who differ from him in their calculation of the length of the average period between new-moon and new-moon by two-fifths of a second only!

OUR BOOK SHELF.

Elements of Physiography. By Hugh Dickie, LL.D. Collins Science Series. (London: Collins.)

THIS is a small manual designedly written as a text-book for the elementary stage of physiography, according to the syllabus of the Science and Art Department. All that is necessary for this stage is treated of within its pages in as concise and brief a manner as possible.

Interspersed amongst the text are upwards of 100 excellent illustrations and four coloured maps, and very good sets of questions for exercise are inserted at the end of each chapter.

The author would do well to be a little more precise and accurate in some of his statements. In Article 150, p. 138, he says: "The position of a star in the sky is fixed as follows:—(1) Its angular distance E. or W. of the line passing through the poles." Which particular one of the infinite number of lines passing through the poles is meant is not very clear. He should have "fixed" the line by adding "and the zenith." At the end of Article 154 he states that "comets and nebulæ are bodies less dense in their composition than stars, and more erratic in their movements." Surely the author should know that nebulæ do not appear to wander about amongst the stars, but keep the same relative position with respect to the latter.

Upon the whole, however, the book, which is moderate in price, can be recommended to pupils preparing for the examination in elementary physiography.

Seventh Annual Report of the Bureau of Ethnology to the Secretary of the Smithsonian Institution, 1885-86. By J. W. Powell, Director. (Washington: Government Printing Office.)

THE Report which occupies the first part of this handsome volume is too old to be read with much interest. Happily it is accompanied by papers which are of more than passing value. One of these—on Indian linguistic families of America north of Mexico—is by Prof. J. W. Powell, who, in the course of an elaborate discussion and exposition, throws much light on an intricate and most difficult subject. A paper by Mr. W. J. Hoffman on the Midē'wiwin or "grand medicine society" of the Ojibwa, will be read with pleasure by students of anthropology, and Mr. James Mooney devotes a very careful and interesting paper to the consideration of the sacred formulas of the Cherokees.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

A Remarkable Rainfall.

I SEND a few particulars of the recent remarkable rainfall at Crohamhurst, situated on the western slope of Mont Blanc, a peak on a spur of the D'Aguilar Range, an offset from the Blackall Ranges, South Eastern Queensland. The whole of this district is watered by the Stanley River, a tributary of the Brisbane River, and hence the values given below were prominent factors in producing the terrible floods from which we have suffered. I may mention that the observer at Crohamhurst is Mr. Inigo Owen Jones, one of my specially trained assistants, and that implicit reliance can be placed on his figures.

The following are the more remarkable falls of the flood period at Crohamhurst:—For 24 hours ending 9 a.m. February 1, 10·775 inches; ditto February 2, 20·056 inches; ditto February 3, 35·714 inches; ditto February 4, 10·760 inches. The gauge is a standard of the "eight-inch" pattern, standing one foot above the ground at an altitude of about 1400 feet above mean sea level. The approximate latitude and longitude of Crohamhurst are 26° 50′ S. 152° 55′ E. The gauge was emptied every three hours, night and day, on the occasion of the greatest fall. I think meteorologists will agree that for a 24 hours' fall we have beaten the world's record.

CLEMENT L. WRAGGE,
Government Meteorologist of Queensland (late of Ben Nevis).

Brisbane, March 22.

The Cold Wave at Hongkong, January 1893.—Its After Effects.

NOW that the cold wave has completely passed away and warm weather is setting in (March 17, 1893), one can write more certainly respecting the effects upon animal and vegetable life.

With regard to the plants the effect has been disastrous, especially on the higher levels, and were it not that our rarest plants descend the hillsides, and often occur in sheltered nooks, this year's frost would have caused the extinction of several of them. Combined with the dry weather we have been enduring the frost has turned our fairly green island into a brown, desert-looking land, much of the undergrowth being dead. Most of the leaves have fallen, even new leaves that were unfolding have been shed, and only now is a fresh crop coming on. The common *Lantana Camara*, instead of being a blaze of bloom, is a ragged, almost leafless shrub, with here and there a flower-head; *Mimosa pudica* is in many cases killed outright, but some are putting out fresh leaves from the root stocks. *Rhodomyrtus tomentosa*, perhaps our commonest shrub, is quite killed on the hills, and the exquisite *Enkyanthus quinqueflorus*, with its pink bells and opal glands, that is so cherished by the Chinese at their New Year Festival (February 17) was hardly up to date. On February 28, with a party of naval officers, I ascended Lanto (3000 feet), a peak on an island near Hongkong, that is famous for Tiu Chung-fa, to give it the native name, and though I found numbers of the shrubs putting forth new red terminal leaves, only one was in flower, and the supply has been very scanty. Cocoa-nuts and bananas have suffered greatly.

At Canton Dr. Henry reports the banana plantations are ruined, and bamboos have suffered. "*Aleurites triloba* (the candle-nut) looks shrivelled up, while begonias, euphorbias, crotons, and scores of others look shrivelled up." There the plants suffered more than at Hongkong, for Mr. C. Ford, superintendent of the Botanic Gardens, reports Aleurites uninjured below an altitude of 300 feet. In his Government report he gives a list of over eighty species of exotics that have suffered, and the following effects upon indigenous plants:—

Bischoffia javanica, Blume	Killed.
Blechnum orientale, Linn.	,,
Embelia Ribes, Burm.	Leaves killed.
ovata, Scheff.	,, ,,
Evodia triphylla, A. de C.	,, ,,
Ficus retusa, Linn.	Killed.
hispida, Linn.	,,
Harlandi, Benth.	,,
Garcinia oblongifolia, Champ. ...	Leaves killed.
Itea chinensis, Hook. and Arn. ...	,, ,,
Melastoma candidum, Don	Killed.
Mœsa sinensis, A. de C.	,,
Nephrolepis exaltata, Schott	Fronds killed.
biserrata, Schott	,, ,,
Psychotria elliptica, Ker	Leaves ,,
Rottlera paniculata, Juss.	,, ,,
Rhodomyrtus tomentosus, Hassk ...	Killed.
Sponia velutina, Planch	,,
Tetracera sarmentosa, Vahl	Leaves killed.
Zanthoxylon nitidus, A. de C. ...	,, ,,

"Those which were killed were above 800 feet above sea-level."

The effect upon insect life has been disastrous. A few straggling butterflies and hymenoptera lasted a few days, and then came a blank of weeks when not an insect of any kind was seen, and the place seemed painfully still from the absence of cicadas by day and crickets by night. My friend Mr. H. E. Denson found a glow-worm at the Peak on February 6, but saw nothing else in the way of insects.

Towards the end of February the weather began to be mild, though it is still below normal, and insects began to appear, some lepidoptera emerging crippled. Butterflies are still quite rare, and generally only single specimens seen. The only species as plentiful as usual is the little pale blue *Lycæna argea*. Last year butterflies absolutely swarmed. Thus Mr. J. J. Walker, R.N., has in his diary the following notes:—February 3. "Euplœas in greater numbers than I had ever seen." And again, March 4: "The profusion of butterflies was quite bewildering."

I cannot show the difference between the two seasons better than by comparing the list of species on the wing:—

Species.	1892	1893	Remarks.
1. *Danais genutia*, Cram. ...	c	—	—
2. *similis*, Horsf. and Moore	c	—	In swarms, 1892.
3. *grammica*, Butl.	v.c	—	In swarms, 1892.
4. *tytia*, Gray	r	—	—
5. *Euplœa superba*, Herbst. ...	v.c	r	One only, 1893.
6. *lorquinii*, Feld.	v.c	—	Swarms in 1892.
7. *Melanitis leda*, Linn. ...	v.c	r	One only, 1893.
8. *Mycalesis mineus*, Linn. ...	c	—	—
9. *Ypthima*	c	—	—
10. *Clerome eumæus*, Drur. ...	v.c	—	—
11. *Vanessa charonia*, Drur. ...	c	r	A few, 1893.
12. *Junonia asterie*, Linn. ...	c	r	A few, 1893.
13. *lemonias*, Linn.... ...	v.c	r	One only, 1893.
14. *orithya*, Linn., var. *Andromeda*	c	—	—
15. *Symbrenthia hypælus*, Hub.	c	r	—
16. *Ergolis ariadne*, Linn. ...	r	—	—
17. *Neptis eurynome*, Westw. ...	v.c	r	—
18. *Athyma perius*, Linn. ...	c	r	A few, 1893.
19. *sulpitia*, Cram.	c	—	—

52. *bianor*, Cram.	c	r	A few, 1893.
53. *Leptocircus*, sp.	c	—	—
54. *Choaspes*, sp.	r	—	—
55. *Baoris mathias*, Fabr. ...	r	—	—
56. *Telicota bambusæ*, Moore. ...	c	—	—
No. of species on the wing, March 17, 1892	56		
No. of species on the wing, March 17, 1893	21		

The paucity of species this year does not nearly represent the difference, for whereas butterflies swarmed at this time last year, they are very rare now. Mr. Walker and I make it a rule to go out every day and note the species, and I do not think we have missed one. It is not the lack of flowers, for the gardens are aglow, and rhododendrons are superb. I may mention that our unique *Rhodoleia Championi* flowered magnificently in February, producing two crops of flowers one after the other; the first were damaged and snapped off short at the base of the peduncle, carpeting the ground with carmine blossoms; the second blooms were not shed.

Bees are now active, cicadas and grasshoppers beginning to sing, but in diminished numbers. Hemiptera are waking up from their torpor, and coleoptera becoming numerous. I imagine there is not a great destruction of pupæ and eggs, but that they are delayed in emerging. To-day we have the first real soaking rain for months, and as the south-west monsoon has begun to make itself felt, I anticipate quite a burst of life during the next few weeks, and will report.

Another interesting phenomenon has occurred since I wrote my first account of the cold wave. The sea-water flowing from the north has cooled below the normal, and at the end of February was as low as 57° F., but has since recovered. Thousands of fish died, or floated about torpid, the critical temperature having just been reached. This state of things lasted about three days. The Chinese fishermen said the fish had cholera, and called attention to some alteration in a joss-house on an island in the harbour, any tampering with which causes sickness to man or beast, by interfering with the Fung Sui! They gave up fishing for a week, but the fish were not diseased so far as I could see.

I may note that since the Sanguir eruption in July last we have had perfect Krakatão sunsets, which are only just waning. They were in greatest force in the middle of December, and the fine after-glow was visible at the zenith an hour and a half after sunset. It was strong enough to overpower the zodiacal light. SYDNEY B. J. SKERTCHLY.

Kowloon, Hongkong, March 17.

P.S.—Mr. J. J. Walker, R.N., has just visited the Happy Valley after the rain. He finds the butterflies much more plentiful. *C. cumæus*, and *H. glaucippe* have appeared within the last two days.—March 23.

The April Meteors.

OF the periodical meteor showers I believe that, from an observational point of view, the April Lyrids may be regarded as one of the least interesting. The display frequently disappoints expectation, and even on the night of April 20, which usually supplies the maximum, the observer often finds his patience taxed in watching a sky which gives not more than seven or eight meteors per hour from all radiants, and not more than one-third of these from the special shower of Lyrids. This is not, however, the invariable experience. Occasionally, as, for example, in 1863 and 1884, the display is a conspicuous one, and rivals other prominent showers, such as the Perseids, Orionids, and Gemmids.

This year the circumstances were not altogether favourable for observation, the crescented moon being visible on April 19 and 20 during the first half of the night, and on April 21 her setting did not take place until 14h. The sky was however clear on April 18, 20, and 21, and the period was a remarkable one on account of its exceptional heat. The maximum shade temperature on four consecutive days was registered here as follow:—April 19, 75°, April 20, 77°, April 21, 81°, April 22, 78°. The height attained on April 21 is entitled to be regarded as a rare meteorological event. With an atmosphere so salubrious the work of recording meteors was rendered very pleasant, and reminded the observer of night-watches in July and August rather than with experiences comparatively early in the spring.

On April 18 I noted 9 shooting stars in the $1\frac{1}{2}$ hour between 11h. 30m. and 13h., and of these 2 or 3 were Lyrids. The shower was so meagre that it was not thought advisable to watch its progress through the night.

On April 19 the sky was not sufficiently clear for observations.

On April 20, between 11h. 15m. and 14h. 25m., I looked towards the eastern quarter of the sky and counted 18 meteors, of which 7 were Lyrids with a sharply defined radiant at $272° + 33°$. Several meteors were also observed from a contemporary shower at $218° + 33°$ between ϵ and γ Boötis. I saw this shower in 1887 from the same point on April 18–25.

On April 21 the sky was beautifully clear, and I recorded 29 meteors during the 4 hours between 11h. 20m. and 15h. 25m. There were 8 Lyrids which showed very exact radiation from the point $273° + 34°$ and close to the position determined on the preceding night. Several of the Lyrids were fine meteors leaving bright streaks and moving with moderate speed. A minor shower was detected from slow meteors seen on this and the previous night, at $200° + 9°$ between Virgo and Boötes. I do not appear to have noticed this radiant during my observations of the Lyrids in former years.

On April 22 clouds unfortunately prevailed, and the further progress of the display could not be watched.

Taking my observations collectively, I saw 56 meteors in watches extending over $8\frac{1}{2}$ hours on the nights of April 18, 20, and 21. Of these about 18, or one-third of the whole, belonged to the Lyrid shower. The apparent paths of the brighter meteors recorded were as follows:—

Date 1893.	G.M.T. h. m.	Mag.	Path From α δ ° °	Path To α δ ° °	Probable Radiant. ° °	Appearance.
April 18	12 50	1	$254 + 22\frac{1}{2}$	$238 + 29$	$274 + 10$	Slow. B. streak.
,, 20	11 25	1	$240 + 49\frac{1}{2}$	$232 + 54$	$218 + 33$	V. slow.
,, 20	11 56	$1\frac{1}{2}$	$289 + 53\frac{1}{2}$	$300 + 52\frac{1}{2}$	$200 + 9$	Slow.
,, 20	12 39	1	$241 + 26\frac{1}{2}$	$231 + 23$	$272 + 33$	Not swift, streak.
,, 21	12 8	♃	$270 + 44$	$268 + 49\frac{1}{2}$	$273 + 34$	V. slow, streak.

The Lyrid seen on April 21 at 12h. 24m. was very brilliant, and it left a long streak between α and β coronæ and slightly above Arcturus. As the meteor traversed its course of 30 degrees it exhibited three outbursts of light, and the places where these occurred were indicated by bright knots in the streak.

One of the most important questions in connection with this cometary meteor shower is as to whether the radiant shows a displacement in its position as observed on successive nights. I wrote in NATURE for May 7, 1885, to the effect that my observations on April 18, 19, and 20 of the year mentioned proved a rapid shifting to the eastwards, and even greater than that recognised in the radiant of the July and August Perseids. My later results confirm the supposed displacement, but show that it is far less extensive than that based on the figures obtained in 1885. I append a summary of all my radiants for this shower with the exception of those obtained in the years 1873 and 1874, which were certainly not very accurate owing to my inexperience in the work at that time. In comparing the various positions included in the list, it must be remembered that too much weight should not be given to any one individually, but that the general result deducible from them all will ensure the most trustworthy conclusions. The first position in the list, viz. that for April 18, 1885, is undoubtedly too far west to be consistent with the others, while that for April 19, 1877, is equally too far north. From the distribution of the radiants in right ascension there is striking evidence of displacement. Further observations will be very valuable, especially if made at the beginning and ending of the shower on say April 16, 17, and 22 and 23. But on these nights it is scarcely visible at all, so that it will be advisable to watch for it during the whole night, and perhaps to amalgamate the results for a similar date in several years.

Radiants of Lyrids observed at Bristol.

1885	April 18	260°	+33°
1887	,,	266	+33
1877	April 19	269	+37
1884	,,	269	+33
1885	,,	268	+33
1887	,,	269	+31
1878	April 20	273	+32
1879	,,	272	+33
1885	,,	274	+33
1887	,,	271	+33
1893	,,	272	+33
1878	April 21	272	+32
1893	,,	273	+34
1878	April 22	275	+31

The consistency of the positions on April 20 sufficiently shows that the radiant is sharply defined and that its place may be determined with considerable precision.

In looking over the observations I found two trifling clerical errors in my catalogue of radiants printed in the *Monthly Notices* for May, 1890. Radiant number 102 was seen on April 19, not April 20, 1884, and number 104 on April 21, not April 20, 1878.

I believe this shower lasts from April 16 to 23. On the former date in 1877 I recorded three of its meteors, and the radiant was indicated at $263° + 33°$, but not with certainty.

The very fine meteor of April 15 last, 9h. 52m., seen in many parts of the country, was not an early Lyrid, but appears to have belonged to a radiant in Cassiopeia, and possibly to the same system which furnished the fireballs of April 10, 1874, and April 9, 1876, with radiants at $19° + 57°$ and $17° + 57°$ respectively, according to Von Niessl. A fireball seen on May 30, 1877, had a radiant at $20° + 58°$, which is virtually the same position as the others. I would be glad to hear of any additional observations of the large meteor of April 15, 1893, or of any of the meteors seen at Bristol on the nights of April 18, 20, and 21 last, and referred to in the first of the foregoing tables.

W. F. Denning.

Smithsonian Institution Documents.

I do not know whether your numerous readers realise that many of the public documents published by the United States Government and the Smithsonian Institution can be obtained by direct personal application to the author, at least as long as copies remain undistributed.

The volume entitled "Mechanics of the Atmosphere," recently published by the Smithsonian Institution, was compiled in the confident hope of stimulating the study of this difficult subject by English-speaking scholars throughout the world; further volumes will follow if it becomes evident that this hope is being realised. This collection of translations appeals especially to the mathematical physicist, and I should be pleased to hear from any one who desires to study or teach this subject.

Cleveland Abbe.

Weather Bureau, Washington, April 15.

THE GENESIS OF NOVA AURIGÆ.

It is a common belief that everything is created for a beneficial purpose, and a commoner one that the chief purpose is the delectation of mankind. Without occupying the stilted position involved in the acceptation of such an idea, it can be said that all things that are made are useful for the extension of knowledge. Viewed from this standpoint, the universe is a field containing an infinite number of facts which have to be reaped and garnered before they can be threshed. In the case of the new star that appeared in Auriga last year, a rich harvest of facts has been gathered in. Astronomers from their watch-towers have scanned the celestial visitor through optic-glasses; estimated its glory; measured its place; photographed it, and caused it to weave its pattern in the spectroscope. But it is not enough to make observations and store them up in musty libraries without the proper understanding of their import. At all events, the greatest possible good should be wrung from the facts, and an attempt should be made to discriminate the theory that best explains them. For this reason the subject of Nova Aurigæ is here resuscitated. Theories galore have been propounded to account for that star's genesis, and the most important are described in this note, so that every one can judge for himself the explanation which sufficiently satisfies the phenomena.

Before the advent of the new star of 1866 the general opinion was that such objects represented new creations. Spectroscopic observations then caused a revulsion of that idea, and we find Dr. Huggins suggesting in an italicised expression, that "*the star became suddenly enrapt in burning hydrogen*" ("Spectrum Analysis," p. 28, Huggins, 1866). To quote more fully, "In consequence it may be of some great convulsion, of the precise nature of which it would be idle to speculate, enormous quantities of gas were set free. A large part of this gas consisted of hydrogen, which was burning about the star in combination with some other element. This flaming gas emitted the light represented by the spectrum of bright lines. The greatly increased brightness of the spectrum of the other part of the star's light may show that this fierce gaseous conflagration had heated to a more vivid incandescence the matter of the photosphere. As the free hydrogen became exhausted the flames gradually abated, the photosphere became less vivid, and the star waned down to its former brightness." More or less modified forms of this theory of a fiery cataclysm were afterwards put forward, to account for the formation of Nova Cygni in 1876. Mr. Lockyer, however, advanced the idea that the outburst was due to cosmical collisions (Nature, vol. xvi. p. 413). In his words, "We are driven from the idea that these phenomena are produced by the incandescence of large masses of matter because, if they were so produced, the running down of brilliancy would be exceedingly slow. Let us consider the case, then, on the supposition of small masses of matter. Where are we to find them? The answer is easy: in those small meteoric masses which an ever-increasing mass of evidence tends to show occupy all the realms of space." Practically all the theories with regard to the origin of new stars are modifications of one or the other of these; either an internal convulsion, or an external collision, is hypotheticated. Let us see how each will stand the test put upon it by Nova Aurigæ.

The discovery by Mr. Lockyer that the bright lines in the spectrum of the new star were accompanied by dark lines on their more refrangible sides seemed at once to be a striking confirmation of his views. The interpretation naturally put upon such a composite appearance was that two discrete masses were engaged in producing the body's light; one, having a spectrum of dark lines, was rushing towards the earth, while the bright-line star or nebula was running away. As Mr. Lockyer remarked in a paper communicated to the Royal Society on February 7, 1892, "the spectrum of Nova Aurigæ would suggest that a moderately dense swarm [of meteorites] is now moving towards the earth with a great velocity, and is disturbed by a sparser one which is receding. The great agitations set up in the dense swarm would produce the dark-line spectrum, while the sparser swarm would give the bright lines." In spite of its simplicity, however, and its ability to account for the observed facts, the meteoritic theory did not commend itself to the minds of some astronomers. Dr. Huggins clung to the idea that the outburst was the result of eruptions similar in kind to those upon the sun, but the acquisition of knowledge of the light changes of stars forced him to withdraw the original suggestion that the luminosity of a Nova is produced by chemical combustion (*Fortnightly Review*, June 1892, p. 827), in fact, to relinquish entirely the crude conception of a burning world propounded in 1866. In its place Dr. Huggins put the view that Nova Aurigæ owed its birth to the near approach of two gaseous bodies. "But," he admits (*Ibid.* p. 825), "a casual near approach of two bodies of great size would be a greatly less improbable event than an actual collision. The phenomena of the new star scarcely permit us to suppose even a partial collision, though if the bodies were diffused enough, or the approach close enough, there may have been possibly some mutual interpenetration and mingling of the rare gases near their boundaries."

"An explanation which would better accord with what we know of the behaviour of the Nova may, perhaps, be found in a view put forward many years ago by Klinkerfues, and recently developed by Wilsing, that under such circumstances of near approach enormous tidal disturbances would be set up, amounting, it may be, to partial deformation in the case of a gaseous body, and producing sufficiently great changes of pressure in the interior of the bodies to give rise to enormous eruptions of the hotter matter from within, immensely greater but similar in kind to solar eruptions." Serious objections to the Klinkerfues-Wilsing hypothesis are pointed out by Herr Seelinger (*Astr. Nach.*, No. 3118, and Nature, December 8, 1892). He shows that the statical theory of tides that has been applied is entirely inappropriate to the case, and also that the hypothesis involves assumptions amounting almost to impossibilities. In the first place, the pairing of the bright and dark lines makes it necessary to assume that the two bodies engaged were of similar chemical constitution, one having an absorption spectrum and the other an equivalent radiation spectrum. But even if we make this unthinkable supposition, a fatal objection has been pointed out by Mr. Maunder (*Knowledge*, June 1892). It is that the bright lines ought to have their refrangibility increased, not decreased as the spectroscopic observations show them to be. In other words, the erupted matter would approach the earth, not recede from it. This single undisputable fact effectually disposes of the chromospheric hypothesis to which reference has been made.

Another chromospheric theory in which only a single star is involved has been put forward by Father Sidgreaves (*The Observatory*, October, 1892). After describing the spectrum he says, "It is only necessary, therefore, to consider the conditions under which the blue-side shift of the Nova's lines should produce the absorption effect while the red-side parts show unclouded radiation. A great cyclonic storm of heated gases would produce this double if the heated gases were rushing towards us in the lower depths of the atmosphere trending upwards and returning over the stellar limb. In the lower positions the advancing outrush would be screened by a great depth of absorbing atmosphere, while as a high retreating current its radiation would be along a clear line to our spectroscopes." This explanation is plausible enough, but it does not go to the root of the matter. How, for instance, does Father Sidgreaves account for such a tremendous eruption as that required by his hypothesis? It is difficult to believe that internal forces could sustain, for two months, a stream of gas rushing earthwards with a velocity of about 400 miles per second, and then curving round and receding at the rate of 300 miles per second. And the idea becomes still more incomprehensible when we remember that the body possessing this marvellous store of energy was quite invisible before December, 1891. Until Father Sidgreaves explains the machinery by which the terrific whirl of chromospheric matter was started and kept up, his theory can hardly be seriously discussed.

As has already been remarked, Mr. Lockyer was the originator of the theory that Novas represent the result of the collisions of small masses. On this theory the broadened character of the lines in the spectrum of Nova Aurigæ is explained by supposing that different parts of the colliding swarms of meteorites were moving with different velocities, or with the same velocity in different directions. Several modifications of the meteoritic theory have been published. Mr. W. H. Monck has suggested that a star, or a swarm of meteors, rushing through a gaseous nebula afford the best explanation of the phenomena. The only difference between this idea and that of Mr. Lockyer's is that the nebula is supposed to consist of gaseous instead of meteoritic particles. But, from a dynamical point of view, there is no distinction between the two, for it is well known that Prof. G. H. Darwin has proved that the individual meteorites of a swarm would behave like the individual particles of a gas. Referring to the collision with a gaseous nebula, Mr. Monck says (*Journal of the British Astronomical Association*, January, 1893): "The previous absence of nebular lines, even if clearly proved, would not be conclusive as to the non-existence of such a nebula, for its temperature may not be high enough to produce these lines until raised by the advent of the star. A considerable proportion of Novæ, however, appear to be connected with known nebulæ. Irregularities in the nebulæ would produce the observed fluctuations of light, and if the relative velocity was considerable the bright gas-lines of the nebula would be distinguishable from the dark absorption lines of the star. The bright lines would be broader than usual, because the velocity of the portion of the nebula adjoining the star would be partially destroyed and the luminous gas would thus be moving with different velocities. The heating being confined to the surface of the star, the cooling would take place more rapidly than after an ordinary collision. But if the star travelled far through the nebula in a state of intense incandescence, portions of the surface would from time to time be vaporised and captured by the nebula, the mass of the moving star thus diminishing at every step. It might even end in complete vaporisation, as meteors are sometimes vaporised in our atmosphere. Herr Seelinger has worked out mathematically a theory (*Astr. Nach.* No. 3118, and NATURE, vol. xlvii. p. 137) very similar to that of Mr. Monck. He supposes that a body enters a cosmic cloud, such as Dr. Max Wolf's photographs show to be widely scattered through space. Whatever the constitution of such a nebulous mass, collision with it causes an increase of temperature, and a vaporisation of some of the constituents of the colliding body. The process is precisely similar to the entrance of a meteor into the earth's atmosphere. According to Herr Seelinger, Nova Aurigæ was produced in this wise. A dark body was rushing earthwards through space; it came to a mass of nebulosity, the light of which was so feeble that the eye could not appreciate it; the collision caused an increase of temperature and of luminosity; the heaping up of the glowing vapours in front of the colliding body produced the spectrum of dark lines, and the bright-line spectrum was given by the vapours left behind as the body moved onwards. These vapours would quickly assume the velocity of adjacent parts of the nebula, hence the dark lines would appear on the more refrangible sides of the bright ones in the manner observed.

Mr. Maunder also favours a collision theory (*Knowledge*, June 1892), his idea being that a long and dense swarm of meteors rushed through the atmosphere of a star, and produced the phenomena exhibited by Nova Aurigæ As the stream passed periastron, the spectrum of the glowing meteorites, and that of the constituents of the stellar atmosphere with which they were colliding, would appear together with the absorption spectrum of the star.

From what has been said it will be seen that none of the collision theories are substantially different from that laid down by Mr. Lockyer in 1877. It has been asserted that the meteoritic theory is not competent to explain the observed facts, but the opponents have generally omitted to specify its imperfections. One of the commonest objections is that the collision of two meteor swarms would be accompanied by a very considerable slackening of the rate of movement. Against this can be urged Seelinger's proof that the great relative velocity indicated by the spectrum could remain practically unchanged, and, in spite of this, enough kinetic energy could be transformed into heat to cause a superficial incandescence. Another objection is that it is impossible to conceive of meteor swarms of such magnitude that though rushing through one another with a relative velocity of more than seven hundred miles per second, disentanglement did not take place until two or three months had elapsed. In the light of latter-day revelations of astronomical photography, this objection becomes a mere cavil. The long-exposure photographs taken in recent years show that space is full of nebulous matter, and the "stream of tendency" is towards the idea that such masses are not gaseous but of meteoritic constitution. Now a simple calculation proves that even if Nova Aurigæ had a parallax of one second of arc, the whole of the luminosity received up to the end of April, 1892, could have been produced by the collision of two bits of nebulous matter, each of which would subtend an angle at the earth of less than half a minute of arc.

Surely it is not too much to assume the existence of meteoritic swarms of such comparatively small dimensions.

In some incidental remarks upon temporary stars, Mr. Maunder agreed with Mr. Lockyer in 1890 (*Journal of the British Astronomical Association*, vol. i. No. 1, p. 29) that they "must be stars in quite another sense to our sun. The rapidity with which their brightness diminishes is plain proof of this. Only small bodies could cool so rapidly, and since despite their vast distance (for their parallax is insensible) these Novas show themselves conspicuous, we are obliged to explain their brilliancy by considering them as consisting of aggregations of such small bodies; the total extent and mass of the swarm making up for the insignificant size of its components."

It will be seen that Mr. Lockyer's theory fits in with these observations most aptly. "New stars," he says (Roy. Soc. Proc., vol. xliii. p. 154), "whether seen in connection with nebulæ or not, are produced by the clash of meteor swarms. Clearly, as the swarm cooled down after the collision, we should find its spectrum tend to assume the nebular type." It is quite immaterial whether the chief nebular line is considered to be due to magnesium or not. According to the meteoritic hypothesis, a new star, as it diminishes in brilliancy, and presumably in temperature, must degrade towards the condition of a nebula. Accept the observations in proof of such a transformation, and the idea that nebulæ are entirely composed of glowing gas becomes untenable, unless it is believed that a Nova increases in temperature as it diminishes in brightness. On the other hand, the change of a new star into a nebula gives strong support to Mr. Lockyer's view that nebulæ are low temperature phenomena. In a paper "On the Causes which Produce the Phenomena of New Stars" (Phil. Trans., vol. clxxxii. (1891) A. pp. 397–448) Mr. Lockyer shows that the spectroscopic observations of Nova Coronæ, Nova Cygni, and Nova Andromedæ are in agreement with his hypothesis. It was therefore expected that Nova Aurigæ should assume the characteristic badge of a nebula. The expectation has been strikingly realised. In August, 1892, the star revived, and on the 19th of that month Prof. Campbell, of the Lick Observatory, wrote the following account of his observations of it (*Astr. Nach.*, No. 3133):—"The brightest line previously observed was resolved into three lines, whose wave-lengths were about 501, 496, and 486, which were at once recognised to be the three characteristic nebular lines. The same morning Prof. Barnard, using the 36-inch equatorial, observed the Nova as a nebula 3″ in diameter, with a tenth magnitude star in its centre. Thus the nebulous character of the object was independently established by two entirely different methods." Writing on the same subject, Prof. Barnard remarks (*Astr. Nach.*, No. 3143):—"I think it unquestionable that had any decided nebulosity existed about the star at its first appearance, it would have been detected in observations with the 36-inch, especially when the star had faded somewhat. So it is clearly evident that there has been an actual transformation in every sense of the word of a star into a nebula within an interval of only four months." Herr Renz has also observed the nebular character of the Nova by means of the Pulkowa refractor. On the other hand, one or two observers have been unable to detect the nebulosity, and it does not appear on Dr. Roberts's photograph of the region. It is impossible, however, to think that an observer of Prof. Barnard's calibre could have been deceived in the matter; hence the conflicting observations are probably accounted for by fluctuations in the extent and brightness of the nebulosity. The fact that Dr. Max Wolf's photographs of the Nova fail to show any haziness round the star goes for nothing, for a patch 3″ in diameter could not be distinguished from a point upon the scale of his pictures.

The spectroscopic evidence of the nebular character of Nova Aurigæ in its old age does not rest merely upon Prof. Campbell's observations. Prof. Copeland examined the spectrum on August 25 and 26, and also Mr. J. G. Lohse. From the measures obtained the mean values assigned to the two brightest lines were λ 500·3 and λ 495·3, while a fainter line was seen in the position λ 580·1, which is also the position of a bright line found in the Wolf-Rayet stars and Nova Cygni (NATURE vol. xlvi. p. 464). Mr. Fowler has also observed the two lines at 5006 and 4956 (*Ibid.* vol. xlvii. p. 399). But perhaps the most convincing of all testimonies is contained in a paper by Herr Gothard on the spectrum of the new star in Auriga as compared with the spectra of planetary nebulæ (Monthly Notices R.A.S., vol. liii. p. 55). The author has photographed the spectra of a number of nebulæ, and compared the results with his photographs of the Nova spectrum. "Each new photograph," says he, "increased the probability, which may be considered as a proved fact that the *spectrum not only resembles, but that the aspect and the position of the lines show it to be identical with the spectra of the planetary nebulæ*. In other words the new star has changed into a planetary nebula." In the face of this array of facts nothing could appear to be more satisfactorily established than the descent of the Nova to the condition of a nebula. Up to the present only one observer, Dr. Huggins, has delivered himself of a contrary conviction. His observations have led him to believe that "the bright band in the Nova spectrum is resolved into a long group of lines extending through about fifteen tenth-metres" when a high dispersion is employed (*Astr. Nach.*, No. 3153). This observation, however, has not been confirmed, hence it cannot be "implicitly accepted." It can hardly be discussed until Dr. Huggins gives a more explicit description of the number and positions of the individual lines he has seen.

Such are the theories with regard to the origin of Nova Aurigæ and new stars generally. From the survey we see that Huggins' theory of burning worlds suggested to account for the appearance of a new star has gone the way of Tycho Brahe's idea that such bodies are new creations. Any and all chromospheric theories fail to explain the transformation of the Nova into a nebula, so they should be abandoned. And finally, the whole sequence of spectroscopic phenomena is explainable on the hypothesis that the light was produced "by the clash of meteor-swarms." From the point of view of the meteoritic hypothesis things could hardly have turned out more satisfactorily than they have, yet at least one carping critic, after being forced to admit the testimony of his eyes that the Nova now exists as a nebula, has ventured to say that the fact tells against it. How, forsooth? Simply to make such a statement without backing it up reminds one very forcibly of mud-throwing. Let the blows to the hypothesis be fairly given, and as fairly met, for only by such means can the truth prevail.

RICHARD A. GREGORY.

THE ROYAL SOCIETY SELECTED CANDIDATES.

THE following fifteen candidates were selected on Thursday last (April 27) by the council of the Royal Society, to be recommended for election into the Society. The ballot will take place on June 1 at 4 p.m We print with the name of each candidate the statement of his qualifications.

WILLIAM BURNSIDE, M.A.,

Professor of Mathematics at the Royal Naval College, Greenwich. Formerly Fellow of Pembroke College, Cambridge Author of the following papers among others:—"On Deep water Waves resulting from a Limited Original Disturbance," and "On the small Wave-Motions of a Heterogeneous Fluid under Gravity" (Proc. Lond. Math. Soc., vol. xx.); "On Functions determined by their Discontinuities and by a Certain Form of Boundary Condition," and "On a Certain Riemann's Surface" (*ibid.*, vol. xxii.); "On a Class of Automorphic Functions," with a "Further Note," and "On the Forms of Hyperelliptic Integrals of the First Class, which are Expressible as the Sum of Two Elliptic Integrals" (*ibid.*, vol. xxiii.); "The Elliptic Functions of $\frac{1}{3}$ K., &c.;" "Centre of Pressure of a Plane Polygon" (*Messenger of Math.*, vol. xii.); "On Certain Spherical Harmonics" (*ibid.*, vol. xiv.); "On the Trisection of the Period for Weierstrass's Elliptic Functions" (*ibid.*, vol. xvi.); "On the Potential of an Elliptic Cylinder" (*ibid.*, xviii.); "Geometrical Interpretation of a Condition of Integrability;" "The Lines of Zero Length on a Surface as Curvilinear Co-ordinates;" "On the Propagation of Energy in the Electro-Magnetic Field" (*ibid.*, vol. xix.); "On the Addition-Theorem for Hyperbolic Functions;" "On a Case of Streaming Motion;" "A Property of Linear Substitutions;" "A Property of Plane Isothermal Curves;" "On the Differential Equation of Confocal Sphero-Conics" (*ibid.*, vol. xx.); "On the Jacobian of Two Quadratics and a System of Linear Equations," "On the Form of Closed Curves of the Third Class;" "On Linear Transformations of the Elliptic Differential" (*ibid.*, vol. xxi.); "On the Division of the Elliptic Periods by 9" (*ibid.*, vol. xxii.); "On the Partition of Energy Between the Translatory and Rotational Motions of a Set of Now Homogeneous Spheres" (Edin. Trans., 1888); "On a Simplified Proof of Maxwell's Theorem (in the Kinetic Theory of Gases)" (Edin. Proc., 1887); "On the Theory of Functions" (Camb. Phil. Proc., vol. vii.).

WYNDHAM R. DUNSTAN, M.A.,

Professor of Chemistry to, and Director of the Research Laboratory of, the Pharmaceutical Society of Great Britain. Lecturer on Chemistry in the Medical School, St. Thomas's Hospital. Author of numerous papers on Chemistry and Chemical Pharmacology, *e.g.*:—"The Action of Alkalis on the Nitroparaffins"; "The Physiological Action of the Paraffinic Nitrites" (Proc. Roy. Soc., 1891—the first of a series of papers in conjunction with Prof. Cash, F.R.S.); "Contributions to our Knowledge of the Aconite Alkaloids"; "The Occurrence of Skatole in the Vegetable Kingdom"; "The Constituents of the Artificial Salicylic Acid of Commerce and a method of producing the pure acid for medicinal use." Distinguished as an Investigator, and for the interest which he has taken in Educational Questions.

WILLIAM ELLIS,

F.R.A.S., F.R. Met. Soc., Memb. Inst. Elect. Eng., late President of Roy. Meteorol. Soc., Superintendent of the Magnetical and Meteorological Department, Royal Observatory, Greenwich. Connected with the Royal Observatory since 1841, and since 1875 has been Superintendent of the Magnetical and Meteorological Department. For eighteen years previously, in addition to astronomical work, had charge of the Chronometer and Time Signal Department. First showed how completely the long series of Greenwich magnetic observations confirmed the existence of sympathetic variation between solar spots and terrestrial magnetism, for horizontal force as well as for declination. Among other works, carried out, on the English side, the whole of the operations in the telegraphic determination of the longitude of Cairo, in which a submarine line of about 3000 miles in length was used in an unbroken circuit. His discussion of these operations is given in the British "Account of the Observations of the Transit of Venus, 1874." Applied the principle of the galvanic regulation of clocks to the regulation of a chronometer. Was formerly Observer in Durham University Observatory, his astronomical work during this time being published in the *Astronomische Nachrichten*, vols. xxxv., xxxvi., and xxxvii. Is the author of a paper in the *Phil. Trans.* "On the Relation between the Diurnal Range of Magnetic Declination and Horizontal Force, as observed at the Royal Observatory, Greenwich, 1841 to 1877, and the Period of Solar Spot Frequency." Also of papers in the *Memoirs* and *Monthly Notices* of the Roy. Astron. Soc., the *Quart. Journ. Roy. Meteorol. Soc.*, and other scientific journals.

J. COSSAR EWART, M.D.,

Professor of Natural History in the University of Edinburgh. An original investigator in various departments of Zoology and Comparative Anatomy. Author of valuable biological memoirs communicated to the Royal Society and to various scientific journals, his researches on the Locomotive System of the Echinodermata having been selected by the Council of the Royal Society as the subject of the Croonian Lecture of 1881. He was appointed in 1878 to the Chair of Natural History in the University of Aberdeen, and, subsequently, to the corresponding chair in the University of Edinburgh. This last post he now fills. He is a member of the Fishery Board of Scotland, and is at present engaged under the co-operation of the Board in important observations and experiments on the Natural History of the Herring. Author of:—"The Development of the Electric Organ of *Raia batis*"; "The Structure of the Electric Organ of *Raia circularis*"; "The Electric Organ of *Raia radiata*" (Phil. Trans., 1889); "The Structure, Relations, Progressive Development and Growth of the Electric Organ of the Skate" (*ibid.*, 1892; "The Cranial Nerves of Elasmobranch Fishes" (Trans. Roy. Soc., Edin.).

WILLIAM TENNANT GAIRDNER, M.D. (Edin.),

Hon. LL.D. (Edin.). F.R.C.P. (Edin.). Hon. M.D. (Dublin). F.K.Q.C.P. (Ireland), Physician in Ordinary to H.M. the Queen in Scotland. Professor of Medicine in the University of Glasgow. Since his graduation, in 1845, has made numerous contributions to the science of Medicine, more especially in the departments of Pathology, Public Health and Hygiene, and Clinical Medicine. He is generally recognised as one of the foremost physicians of his time, and his status in the profession is indicated by the fact that he has acted as President of the British Medical Association. For several years he acted as the first Medical Officer of Health for the city of Glasgow, and it is well known that the measures he then initiated for securing the health of the community soon materially lowered the death rate of the city, and have been largely adopted both at home and abroad. Dr. Gairdner has held the chair of Medicine in the University of Glasgow for thirty years, and he is distinguished as a teacher as well as an investigator into the phenomena of disease. Dr. Gairdner has published the following works:—(1) "Contributions to the Pathology of the Kidney" (1848); (2) "Pathological Anatomy of Bronchitis and on Bronchial Obstruction" (1850); (3) "Pathology of Pericarditis" (1860); (4) "Clinical Medicine" (1862); (5) "Public Health in Relation to Air and Water" (1862); (6) "Alcoholic Stimulants in Treatment of Fever" (1864); (7) "Study of Fever in Glasgow" (1865); (8) "On Articulate Speech and Aphasia" (1866); (9) "On Antipyretic Treatment of Specific Fever" (1878); (10) "Clinical Lectures" (1877); (11) "Angina Pectoris" in Reynolds's "System of Medicine" (1877); (12) "On the Physiognomy of Disease in Finlayson's Clinical Manual" (1878); (13) "On Insanity" (Morisonian Lectures, 1885); (14) "The Physician as a Naturalist" (1888); and many papers in medical journals, and in the transactions of pathological and medical societies.

ERNEST WILLIAM HOBSON,

D.Sc. (Cantab.). Fellow of Christ's College, Cambridge, and University Lecturer. Author of the following memoirs, paper and book:—"On a Class of Spherical Harmonics of Complex Degree with Applications to Physical Problems" (Trans. Camb. Phil. Soc., vol. xiv.); "Synthetical Solutions in the Conduction of Heat" (Proc. Lond. Math. Soc., vol. xix.); "Systems of Spherical Harmonics" (*ibid.*, vol. xxii.); "On Harmonic Functions for the Elliptic Cone" (*ibid.*, vol. xxiii.); "On a Radiation Problem" (Proc. Camb. Phil. Soc., vol. vi.); "On a Theorem in Differentiation and its Application to Spherical Harmonics" (read before the Lond. Math. Soc., and in the press); "On the Evaluation of a Certain Surface-Integral and its Application to the Expansion of the Potential of Ellipsoids" (read before the Lond. Math. Soc.); "On Fourier's Theorem" (*Messenger of Math.*, vol. xi.). Author of the article "Trigonometry," in the "Encyclopædia Britannica," Author of a treatise on "Trigonometry," including many of the higher developments.

SIR HENRY HOYLE HOWORTH,

Barrister-at-Law. Author of "A History of the Mongols, 4 vols., 1876-87; "The History of Chenghiz Khan and his

Ancestors," containing much information upon the Ethnography of Asia, &c., published in parts in "The Indian Antiquary," and about to be republished separately; "The Mammoth and the Flood," 8vo, pp. 464, 1887. Numerous papers on historical, antiquarian, anthropological, and geological subjects in Journ. Ethnolog. Soc., Journ. Anthrop. Inst. (Westerly Drifting of the Nomads, Ethnology of Germany, Spread of the Slaves, &c.), Journ. Roy. Asiat. Soc. (Northern Frontagers of China), International Congress of Orientalists, Historical Soc. (Early History and Movements of the Danes and Norsemen), Archæologia, Geological Magazine, &c. Distinguished for his literary and archæological attainments.

EDWIN TULLEY NEWTON,

F.G.S., F.Z.S. Palæontologist to the Geological Survey of England and Wales. For twenty-five years on the Staff of the Survey. Recipient of the Wollaston Donation Fund of the Geological Society, in 1884. Author of numerous papers on Palæontological and Biological Subjects, of which the following are some of the more important:—"On the Skull, Brain and Auditory Organ of a New Species of Pterosaurian (*Scaphognathus Purdoni*)" (Phil. Trans., 1888); "On a Gigantic Species of Bird (*Gastornis Klaassenii*) from the Lower Eocene" (Trans. Zool. Soc., 1886); twenty-six papers on "Cretaceous Fishes and Tertiary Vertebrata" (in *Quart. Journ. Geol. Soc.* and *Geol. Mag.*, 1876-90) "On the Structure of the Eye of the Lobster and on the Brain of the Cockroach" (*Quart. Journ. Micros. Sci.* 1873-79). Also the following Memoirs of the Geological Survey:—"The Chimœroid Fishes of the British Cretaceous Rocks" (1878); and "The Vertebrata of the Forest Bed Series of Norfolk and Suffolk."

CHARLES SCOTT SHERRINGTON,

M.B. (Camb.), M.A. Lecturer on Physiology, St. Thomas's Hospital. Author of the following and other papers:—"Secondary and Tertiary Degenerations in the Spinal Cord of the Dog" (*Journ. Physiol.*, 1885); "Degenerations in the Spinal Cord following Lesions of the Cortex Cerebri" (*ibid.*, 1889); "On two recently described Tracts in the Spinal Cord" ("Brain," 1886); "On Outlying Nerve Cells, in the Mammalian Spinal Cord" (Phil. Trans., 1890). Joint Author of the following, and other papers:—"Secondary Degeneration in the Spinal Cord of the Dog" (*Journ. Physiol.*, 1884); "Bilateral Descending Degeneration Fifty-two Days after Hæmorrhage in one Cerebral Hemisphere" ("Brain," 1886); "On the Formation of Scar Tissue" (*Journ. Physiol.* 1889); On the Regulation of the Blood Supply of the Brain" (*Journ. Physiol.* 1890); "The Influence of the Movements of the body upon the Capacity of the Cranio-Vertebral Canal" ("Brain," 1891).

EDWARD C. STIRLING,

M.D. (Camb.), M.A., F.R.C.S., C.M.Z.S., late President, Royal Society of South Australia, and Inter-colonial Medical Congress. Senior Surgeon, Adelaide Hospital. Lecturer on Physiology, University of Adelaide. Eminent for his researches in Physiology and Ethnology in South Australia. Formerly Assistant-Surgeon and Lecturer on Physiology, St. George's Hospital, London. For ten years Surgeon to the Adelaide Hospital, and now Senior Surgeon and Member of the Board of Management. For ten years Lecturer on Physiology and Member of the University Council of Adelaide. President of the First Inter-colonial Medical Congress, 1887; Vice-President of the Second, 1888. President of the Royal Society of South Australia, 1889; and of the Australian Branch of the British Medical Association in 1888. A member of the Legislative Assembly South Australia, 1883-86. First President and Organiser of the States Children Council. For seven years Hon. Director and Organiser of the South Australian Museum. Author of many papers in the St. George's Hospital Reports, Inter-colonial Congresses, the Transactions South Australian Branch Brit. Med. Assoc., Transactions of the Zoological Society, London, and Royal Society of South Australia. Discoverer of a new genus and Species of Marsupialia, *Notoryctes Typhlops*, and other species, during a journey from the north to the south of the Australian Continent, in company with His Excellency the Earl of Kintore, Governor of South Australia.

JOHN ISAAC THORNYCROFT,

M.Inst.C.E. Member of Council of the Institution of Naval Architects. Author of several papers connected with Science, as: "On the Resistance opposed by Water to the motion of Vessels of Various Forms, and on the way in which this varies with the velocity" (1869); "On the Efficiency of Guide-blade Propellors" (1883); "On the most suitable Propellor for Shallow Draughts" (1885); "On Shallow-draught Screw-steamers" (1885); "On Torpedo-boats and Light Yachts" (8vo, pp. 94, with five large diagrams, 1881). A distinguished engineer and naval architect, also most successful as a scientific naval architect in the construction of torpedo-boats, having a minimum of weight and a maximum of power and speed. Attached to science and anxious to promote its progress.

JAMES WILLIAM HELENUS TRAIL,

M.D., A.M., C.M. (Aberdeen). Regius Professor of Botany (since 1877) in the University of Aberdeen. Corresp. K.-K Zool.-Botan. Gesell., Vienna, and Soc. Nat. Sci. et Math., Cherbourg. Made, in 1874, important botanical collections in the Valley of the Amazon, in North Brazil. Author of a paper on the Palms collected on the occasion (Journ. of Bot., 1876); of a "Revision of Scottish *Discomycetes*" (Scottish Naturalist, N.S., iv., 1889); of a paper on the Gall-making Diptera of Scotland (*ibid.*, 1888), and of numerous others.

ALFRED RUSSEL WALLACE,

LL.D., D.C.L., F.L.S., F.Z.S. Author of a paper "On the Tendency of Varieties to depart indefinitely from the Original Type" (Journ. Linn. Soc., iii., 1859, Zoology), and numerous other writings.

ARTHUR MASON WORTHINGTON,

M.A., F.R.A.S. Head Master and Professor of Physics, Royal Naval Engineering College, Devonport. Distinguished as a physicist, especially for his researches on surface tension and on the stretching of liquids. Author of the following papers:—"On the Forms assumed by Drops of Liquid falling Vertically on a Horizontal Plate" (Proc. Roy. Soc., 1876–77); "On the Spontaneous Segmentation of a Liquid Annulus" (*ibid.*, 1879); "On Pendent Drops" (*ibid.*, 1881); "On Impact with a Liquid Surface" (*ibid.*, 1882); "On the Horizontal Motion of Floating Bodies under the Action of Capillary Forces" (Phil. Mag., 1883); "On the Surface Forces in Fluids" (*ibid.*, 1884), "On the Error involved in Prof. Quincke's Method of Calculating Surface Tensions from the Dimensions of Flat Drops and Bubbles" (*ibid.*, 1885); "A Capillary Multiplier" (*ibid.*); "On Tensional Stress and Strain within a Liquid" (Brit. Assoc. Sect. A., 1888): "On the Discharge of Electrification by Flames" (Brit. Assoc., Rept. Electrolysis Comm., 1889); "On the Mechanical Stretching of Liquids, an Experimental Determination of the Volume-Extensibility of Ethyl Alcohol" (read before the Roy. Soc. Feb. 4, 1892). Also of the following:—"Physical Laboratory Practice," and "The Dynamics of Rotation."

SYDNEY YOUNG,

D.Sc. (Lond.). Professor of Chemistry, University College, Bristol. Well known as a scientific chemist. Author of numerous papers on Organic and Inorganic Chemistry, and on the border-land of Physics and Chemistry. Among these are:—"Alkyl Fluorides;" "Ethyl valerolactone;" "Vapour Pressures and Specific Volumes of Halogen Compounds in relation to the Periodic Law;" "A New Method of determining Specific Volumes of Liquids and Saturated Vapours;" "The Molecular Volumes of the Saturated Vapours of Benzene, and of its Halogen Derivatives." Dr. Young is also the joint author of numerous memoirs on the thermal properties of liquids, and allied subjects, several of which have appeared in full in the Philosophical Transactions. During the last five years Dr. Young has published the following papers on chemical and physical subjects:—Preparation of Dibenzyl Ketone; Vapour-Pressures of Quinoline, Dibenzyl Ketone, and Mercury; Exact Thermometry; The Volatilisation of Ice; A Thermometer for Lecture Purposes; Relations between Boiling-Points, Molecular Volumes, and Chemical Characters of Liquids; Vapour-Pressures and Molecular Volumes of Acetic Acid, Carbon Tetra-Chloride, and Stannic Chloride; Relations between "Corresponding" Temperatures, Pressures, and Volumes of Liquids and Vapours. The last item of the series of joint papers with Professor Ramsay—"A Study of the Thermal Properties of Water and Steam"—has been published in the Philosophical Transactions. Dr. Young is also the author of the articles on "Distillation," "Sublimation," and "Thermometry" in Thorpe's "Dictionary of Applied Chemistry."

NOTES.

MR. CHARLES CHREE, Fellow of King's College, Cambridge, has been selected to fill the important office of Superintendent to the Kew Observatory. It is one for which the combination of high mathematical capacity with a practical experience of the apparatus and methods of physical research is especially needed. Mr. Chree obtained in 1884 the hitherto unequalled honour of a first class in the most advanced parts both of the Mathematical and of the Natural Science Triposes, and he has since been much engaged at Cambridge in experimental and mathematical investigations. The results of these are published in the *Cambridge Philosophical Journal*, and in the "Philosophical Transactions" of the Royal Society.

THE "James Forrest" lecture will be delivered at the Institution of Civil Engineers this evening by Mr. William Anderson, F.R.S. The subject is the interdependence of abstract science and engineering.

SIR W. H. FLOWER, F.R.S., will preside over the fourth annual meeting of the Museums' Association, which will be held in London in July. The meeting, which will last for several days, will begin on Monday, July 3.

AT the meeting of the Victoria Institute on Monday a paper by Prof. Maspero was read in the author's absence by Mr. T. G. Pinches, of the British Museum. The paper embodied the results of Prof. Maspero's investigations during the past ten years as regards the places in Southern Palestine claimed, according to the Karnac records, to have been captured by the Egyptians in the campaign under Sheshonq (Shishak) against Rehoboam.

THE report of the Council of the City and Guilds of London Institute has just been published. We are glad to note that they are "able again to point to steady and continued development in each branch of the Institute's work, as shown by the statistics of their colleges, and—what is more satisfactory—by the positions taken by their students, as the result, to a large extent, of the instruction provided."

THE tercentenary of the foundation of the Botanic Garden of Montpellier will be celebrated by *fêtes* from the 20th to the 28th of May, when the Botanical Society of France will hold its special annual session in the town. The botanists of Montpellier offer hospitality to foreign botanists who may desire to attend the *fêtes*.

SINCE the death of Dr. Prantl the editorship of the cryptogamic bi-monthly *Hedwigia* has been undertaken by Dr. G. Hieronymus, Herr P. Hennings, and Dr. G. Lindau.

UNDER the auspices of the Imperial Academy of Sciences in Vienna, Dr. E. v. Halácsy, and Prof. Hilber have undertaken a botanical and geological investigation of Mt. Pindus in Thessaly in the course of the present year.

PROF. MARTIN, on account of his serious and prolonged ill-health, has tendered his resignation of the professorship of biology, which he has held in the Johns Hopkins University since 1876.

A NEW journal of experimental and theoretical physics, called *The Physical Review*, and conducted by Edward L. Nichols and Ernest Merritt, will be published for the Cornell University by Messrs. Macmillan and Co., New York and London. The first number will appear on July 1. The new journal will be issued bi-monthly, and each number will consist of at least sixty-four pages. It will be devoted to the promotion of original work in physics.

THE Camera Club has issued a "Conference Number" of its Journal, in which an account is given of the proceedings of the Photographic Conference, held lately at the Society of Arts.

SINCE our last issue the temperature has appreciably decreased over these islands; the maxima have only reached 70° occasionally in the southern and central parts of England, while in all other districts the thermometer has seldom risen above 60°. Up to Tuesday, the 2nd inst., the rainfall had only been slight, the greater part being confined to the northern and western parts of the country, where small amounts have been of frequent occurrence. The recent drought has been probably unprecedented in some parts; at places on the south coast no rain had fallen for forty-five days, while in the neighbourhood of London there were thirty days without rain. The type of weather has recently undergone an entire change; cyclonic disturbances formed in and near our islands, while the anticyclonic conditions temporarily disappeared. With this change in the distribution of atmospheric pressure, the northerly and easterly winds gave place to those from westerly and southerly directions, unsettled and showery weather became general over the whole country, and the softer quality of the air was very perceptible. Notwithstanding the decrease of temperature, the *Weekly Weather Report* of April 29 showed that it was above the mean in all districts, the excess varying from 3° to 5° in the north and west, to 6° or 7° in most parts of England. The rainfall for the week was, of course, less than the mean in all districts, while bright sunshine was very prevalent over the entire kingdom; in the Channel Islands the percentage of possible duration was as high as 81, and in all districts it greatly exceeded the average.

DR. PAUL SCHREIBER has communicated to the *Meteorologische Zeitschrift* for April an account of some extraordinary snowballs which fell at Glashutte, in Saxony, on December 4 last. After a storm which had lasted ten minutes, a calm suddenly occurred, and light balls of snow measuring from four to five inches began to fall. The balls lay on the ground until the next day, there being from five to twelve of them to a square yard. Dr. Schreiber thinks that the phenomenon was of an electrical origin, as the preceding disturbance seemed to point to a thunderstorm.

PROF. HELLMANN, to whom meteorologists are so much indebted for many laborious investigations into the history of old observations and instruments, has recently made an important addition to early meteorological literature by the publication of *Das älteste Berliner Wetter-Buch*, containing observations made in Berlin in 1700–1701, by Gottfried Kirch and his wife, being the first part of a manuscript of over 1000 quarto pages. During the preparation of Dr. Hellmann's valuable work on the climate of Berlin he had made constant search for these observations, which were known to have been in Berlin about fifty years ago, and he at last discovered them, strangely enough, in the Crawford Library at the Edinburgh University. It is well known that Lord Crawford (then Lord Lindsay) took an interest in collecting works on comets, and these old manuscripts contained a number of such observations, in addition to meteorological data. Dr. Hellmann's account of the search for, and the discovery of, the manuscript, and of the antecedents of the Kirch family, is exceedingly interesting.

IN the *Annales* of the French Meteorological Office, recently published for the year 1890, M. Angot has discussed the observations taken simultaneously during that year at the Central Meteorological Office and on the Eiffel tower, and has arrived at some interesting results respecting the variation with height of the several meteorological elements. The reduced barometric pressure was lower every month on the tower than on the ground, the probable cause being the great difference in the velocity of the wind at the two stations. The observations made at the three stations on the tower allow of the variations of temperature with altitude being studied with great detail, and it was found that the rate of diminution was far from being proportional to the height above the ground. In all months, at the middle of the night-time, the temperature increased with altitude, the maximum difference occurring at a mean height of about 500 feet, it then decreased at first slowly, and afterwards more rapidly; at about 1000 feet the mean rate of decrease already amounted to 1°·4 per 100 metres (328 feet) During the middle of the day-time the decrease of temperature with height above 500 feet is nearly uniform in all months, being about 1°·6 for each 100 metres. Between 500 feet and the ground, however, the decrease showed a marked annual variation; during the cold season the difference was less than that observed at the higher level, while in the hot season it was much greater. The diurnal variation of vapour tension at the summit of the tower exhibited entirely different characteristics from those near the ground; generally speaking, there was only one maximum, near noon, and one minimum, between the evening and midnight. During all months the vapour tension was less at the top of the tower than near the ground. The diurnal variation of the wind exhibited a marked minimum at the top of the tower during the day-time, and a maximum at night, being the reverse of what is observed at ground stations.

THE Board of Agriculture has issued a valuable report on rust or mildew on wheat plants. It contains a complete account of the life-history of the fungus of ordinary mildew, *Puccinia graminis*, as well as of that of spring-rust and mildew, *Puccinia rubigo vera*, with a discussion of the conditions favourable for their propagation, and the best means of averting them. It is illustrated by some excellent coloured plates by Mr. Worthington Smith.

RATHER less than three years ago (NATURE, vol. xlii. p. 297) we had to record the death of Mr. W. K. Parker, and in doing so we gave some account of the main facts of his career. An excellent little biographical sketch of him by his son, T. Jeffrey Parker, has just been published by Messrs. Macmillan and Co. In an introductory letter Prof. Huxley speaks of the volume as one which "gives a presentation as accurate as it is vivid, of a man of noble and lovable character, endowed with intellectual powers of a very unusual order." Prof. Huxley says he has "never met with another such combination of minute accuracy in observation and boundless memory for details, with a vagrancy of imagination which absolutely rioted in the scenting out of subtle and often far-fetched analogies." "The genius of an artist struggled with that of a philosopher, and not unfrequently the latter got the worst of the contest."

AT the instance of some Russian meteorologists, who have frequent occasion to measure very low temperatures, M. Chappuis lately undertook a study of the spirit thermometer (*Arch. de Sciences*). He traces its anomalies to three sources. (1) Adhesion of the liquid to the walls of the capillary tube. When the instrument is brought from ordinary temperature to a lower, the sinking column leaves liquid on the tube, which for hours, and even days, continues slowly descending. (2) Irregular expansion of the spirit with the temperature. As the expansion increases with heating, the graduation should be made to correspond, the degrees for higher temperatures being longer (which is not usually the case). (3) Impurities in the spirit, and varying water-content, which affect expansion materially. M. Chappuis recognises the difficulty of getting rid of these faults, and concludes that alcohol is not to be recommended as a liquid for thermometers marking low temperatures. On the other hand, it has been shown that toluol (with a boiling point of about 110° C.) is a liquid well adapted for the purpose and free from the disadvantages referred to.

LAKE MEMPHRAMAGOG—the Loch Lomond of Canada—lies partly in the State of Vermont, but belongs to the St. Lawrence hydrographic system. It is thirty miles long, and varies from one to four miles in breadth. It lies in the lap of high hills, and is a deep-water lake, soundings in one locality indicating depths, it is claimed, of 600 ft. Mr. A. T. Drummond writes to us that from readings taken on August 10 last, at 11 a.m., under a strong sun and cloudless sky, two facts appear to be established:—(1) that Lake Memphramagog is a cold-water lake whose bottom temperatures are in August as low as 44°·75 Fahr.; (2) that the high surface temperature is only maintained for relatively a few feet, beneath which the mercury falls rapidly towards the lowest reading. There is a decided surface current at the southern end, arising from the inflowing streams there, and it is suggestive the warm waters from these streams flow, river-like, over the colder waters of the lake, just as the Gulf Stream, under a different influence, but lightly skims the surface of such a large portion of the broad Atlantic Ocean. Whilst the thermometer at twelve fathoms registered 51°, the waters of Lake Ontario, at their outlet into the St. Lawrence indicated at the same depth, and at about the same period, 67°.

THE green colour in certain oysters, localised in the gills and palps, and lost under certain conditions, is known to be due to an insoluble pigment introduced by a diatom on which the oysters feed. It has been shown lately by M. Pelseneer, of Ghent (*Rev. Sci.*), that a process of "phagocytosis" here occurs. The pigmentary granulations are an injurious product in the blood; and they are devoured by the blood corpuscles, which, thus charged, pass into the gills and palps, where the blood is separated from the outer water by a mere thin layer of epithelium. The corpuscles penetrate between the epithelial cells, where some are destroyed, and some pass right through and escape. It is thus explained how green oysters placed in water without the diatom referred to lose their colour very quickly (in thirty-six hours at most), the charged corpuscles being rapidly eliminated.

THE success of the luminous fountains at the Paris Exhibition of 1889 suggested to M. Trouvé the idea of producing the effects on a small scale and cheaply. Several forms of this small fountain are described in the *Bulletin de la Société d'Encouragement*. Instead of illuminating the water jets by lateral mirrors, M. Trouvé lights up with an incandescent lamp at the focus of a parabolic mirror a sort of inverted glass with apertures for the liquid. M. Trouvé also here describes his method of imitating lightning at one of the Paris theatres. Instead of flashing lycopodium powder behind a broken line cut in the scenery (the old plan), a long bamboo or other flexible rod is used, having a small incandescent lamp of great brilliancy at the end, with a foot commutator, enabling one to make or break the circuit at will. The rod is moved quickly down in a zigzag direction at the proper moment. The sound of the wind in a storm is imitated by means of a double-action pump and two sirens; and that of hail by throwing coarse sand against an osier screen.

A SIMPLE optical photometer, serving also to measure the degree of visual power, has been devised by Dr. Simonoff

(*Moniteur de la Photogr.*). A series of twenty-four pages is arranged, the first having a clear grey tint, the second one of double intensity, and so on to the twenty-fourth, the tint of which is nearly black, being twenty-four times more intense than that of page 1. On each page are printed a few phrases in black letters of different sizes. In a badly lit room one may estimate the amount of illumination by turning over the leaves of this little book, held about a foot from the eyes, until one can no longer read the line of letters of a selected size. With good illumination you may proceed to the twentieth or twenty-fourth page, but with poorer light you may be stopped at the tenth, or twelfth, or fifteenth. The instrument is for indoor use exclusively. In schools it might prove useful in testing the vision of children.

A PERIODICAL which will show what natives of India can do in some branches of science has been started in Bombay. It is called *The Indian Medico-Chirurgical Review*, and is edited by N. A. Choksy. We have received the third number, in which several native writers record the results of original observation, while there are many good notes on work being done in Europe. In one article the *Review* urges the necessity for the establishment of a teaching university in Bombay. As the teaching of law, medicine, and science in the presidency is practically located in the city of Bombay, and hence in touch with the existing examining University, a few professorships might, the *Review* thinks, be endowed, and eminent men invited from Europe to occupy the new chairs. The *Review* also suggests that the Government might with advantage "copy the system of the German Universities by establishing biological, physiological, pathological, bacteriological, and hygienic institutes, in connection with these professorships, and place over them professors who would go on teaching and at the same time carry on original researches."

IN the report of the Geological Survey of India for 1892 reference is made to Dr. Noetling's visit to the amber and jade mines of Upper Burma—a visit which was rendered possible by the starting of the Maingkwan column. The so-called amber turns out to be a new variety of this form of fossil resin, to which the name of Burmite has been assigned by Dr. Noetling in conjunction with Dr. Otto Helm (a distinguished authority in this line) of Danzig, to whom specimens were forwarded. The peculiarity of Burmite is a fluorescence, giving the mineral an appearance as of solidified kerosine oil: and, as far as has yet been seen, it is of darker colours than is usual with amber proper (succinite); while it is a little harder than the latter. The colour alone is, according to the present fashion in Europe, against the mineral, but some of the darker varieties of brown red colour, present on being cut deeply *en cabochon*, the flat or under face being turned to the observer, a really gorgeous ruby tint which should make the stone desirable ornamentally. The so-called jade—for the actual constitution of the mineral as worked in Burma determines it properly as *jadeite*—is worked by pit and quarry mines, the former for forty miles along the bank of the Uru river southwards from Sankha, while the latter are excavated on the top of a plateau at Tammaw, eight miles out of Sankha, in the Mogoung subdivision. The industry seems to be a thriving one, and rather promising for future more systematic and skilled development, for at least 500 men are engaged every season in working the quarries. White is the commonest colour, the green varieties being of much rarer occurrence; while, in some of the fewer boulders obtained from the laterite beds along the course of the Uru river, a "red jade" appears to have been produced by ferruginous decomposition change.

THERE are two stations in Italy for the economic investigation of the diseases of plants; one at Pavia, established in 1871 in connection with the Botanical Institute of the Royal University, and now under the directorship of Prof. Briosi; the other at Rome, established in 1887, and presided over by Prof. Cuboni. They are required to investigate the nature and cause of diseases, to test and provide remedies, and to disseminate information by lectures and publications. As might be expected, the diseases of the vine and of the olive occupy a large share of their attention.

PROF. V. DVORAK, of Agram, uses a very simple apparatus for demonstrating the oscillation of the air in sound phenomena. In an ordinary resonating sphere the short neck is replaced by a small metal plate with a conical hole opening inwards, its shortest diameter being about 2 mm. When the resonator sounds, the passage of air through the hole is strong enough to extinguish a lighted match. If a small paper wheel resembling a water-wheel is placed a little below the opening and the resonator stands about 3 cm. in front of a wall, the blowing of a horn, or the singing of the proper note, is capable of setting the wheel in rapid rotation. A very serviceable lecture apparatus for measuring the intensity of sound is illustrated in the *Zeitschrift für Physikalischen Unterricht*. A narrow glass tube bent at a very obtuse angle is half filled with alcohol. One end of the tube has a conical opening, and this is placed at a distance of 0·5 cm. from the opening of the resonator described. The whole is mounted on a board capable of adjustment to any angle. The puffs emitted from the resonator when responding to a sound affect the level of the alcohol, and the displacements are read off on a scale attached to the tube, projected, if necessary, on to a screen. Another effect of sound easily observed is that of repulsion. A light resonator of the ordinary construction is floated on water, its axis being kept horizontal by means of an attached piece of wire. On blowing the horn, the sphere will float in the direction opposite to that in which the neck is pointed. To produce continuous rotation, four resonators are attached to a light cross of wood turning on a needle point, or one resonator with four bent necks is suspended by a thread. If this acoustical reaction wheel is placed in one corner of the lecture theatre, it can be set rotating from the opposite corner by a strong tuning fork, or even by singing through a conical tube.

AT the recent exhibition of the Société Française de Physique, M. Hurmuzescu showed the following experiment:—A metallic wire, through which a continuous current is passed, is stretched horizontally in a glass tube containing gas either at the ordinary atmospheric pressure or rarefied. As soon as the wire becomes red-hot it begins to vibrate in a vertical plane, and the containing tube becomes much hotter at the bottom than at the sides. This effect has not been satisfactorily explained by its discoverer.

M. CLAUDE showed at the same exhibition an instrument for measuring the difference in phase between the current in a circuit and the impressed electromotive force. The principle of the instrument is as follows:—When a piece of soft iron, fixed to the end of a spring, is placed before the pole of an electromagnet having a permanently magnetised core and traversed by an alternating current, it is attracted and vibrates with the same period as the current. If the spring also carries a mirror from which a ray of light is reflected on to a scale, the length of the band of light produced will be proportional to the maximum displacement of the mirror. Two such electromagnets are used, acting on the piece of soft iron in opposite directions, and at such distances that they produce the same maximum deflection, one magnet being placed in series with the circuit, and the other joined to the ends of a non-inductive resistance. Under these conditions the length of the band of light is proportional to the cosine of half the angle of lag.

An interesting note by M. Birkeland appears in the *Comptes Rendus* for April 17 on the reflection of electrical waves at the extremity of a linear conductor. By an application of Prof. Poynting's theorem concerning the movement of the energy in an electromagnetic field to the case of a Hertzian oscillator, he has shown how the damping of the oscillations depends on the nature and position of the conductors in the neighbourhood. He also accounts for the fact that, when the distance between the first stationary node and the end of a wire is determined by means of a secondary circuit, the value found is smaller than that obtained by a direct measurement of the potential along the wire, by showing that the paths along which the magnetic energy travels are extended beyond the end of the wire, so that the wave has, so to speak, to make a detour round the end of the wire, and is thus retarded.

An important new series of compounds, the thionylamines, in which two new hydrogen atoms of the amido group of the primary amines are replaced by the radicle thionyl SO, have been prepared by Prof. Michaelis, and are described in the current number of *Liebig's Annalen*. It has been found that the primary amines of the fatty series when dissolved in ether react with thionyl chloride, $SOCl_2$, in a manner which is readily controlled by extraneous cooling of the vessel in which the reaction is conducted. The products are the hydrochloride of the amine employed which separates in crystals, and the new liquid thionylamine which remains dissolved in the ether, but can readily be isolated by fractional distillation. Thionyl chloride is incapable of acting upon the hydrochlorides of the amines of the fatty series, hence three molecular equivalents of the amine are required for every equivalent of thionyl chloride, according to the following equation in the case of methylamine:—$SOCl_2 + 3(CH_3.NH_2) = CH_3.N:SO + 2(CH_3NH_2.HCl)$. The thionylamines of this series are colourless fuming liquids which boil without decomposition and emit a most powerful odour. They are decomposed by water into the original amines and sulphur dioxide. The amines of the aromatic series likewise form thionylamines with thionyl chloride; and the hydrochlorides, unlike those of the fatty series, react with equal facility in accordance with the equation $C_6H_5NH_2.HCl + SOCl_2 = C_6H_5N:SO + 3HCl$. It is only necessary to cover the powdered hydrochloride of aniline with benzene, add the calculated quantity of thionyl chloride, and warm over a water bath for a short time. The lower members of the aromatic thionylamines are yellow liquids which distil without decomposition; the higher members may likewise be distilled without loss under diminished pressure. Alkalies convert them into the original amines and a sulphite, $C_6H_5N:SO + 2NaOH = C_6H_5NH_2 + Na_2SO_3$.

Thionyl-methylamine, $CH_3N:SO$, the first member of the series, is most conveniently prepared by reacting with methylamine upon a solution of thionylaniline in toluene. The latter is first prepared and cooled by a freezing mixture; the methylamine should likewise be maintained at as low a temperature as possible until the moment of adding it to the solution of thionylaniline. After agitation and standing for some time the product of the reaction may be distilled, when thionylmethylamine is obtained as a colourless fuming liquid boiling at 58–59°. Its odour is not unlike that of bleaching powder. Thionyl-ethylamine, $C_2H_5N:SO$, may be readily obtained by mixing cooled ethereal solutions of thionyl chloride and ethylamine. The reaction even at this low temperature is very violent, occurring with hissing and the evolution of white fumes as each drop of the dilute ethereal solution of thionyl chloride falls into the solution of ethylamine. Ethereal solutions of thionylaniline and ethylamine afford a better yield, and with less admixed impurity. Thionyl-ethylamine boils at 73°, and in properties closely resembles thionyl-methylamine. Several of the higher members of this and of the aromatic series have been prepared by Prof. Michaelis, and are fully described in his lengthy memoir. It is interesting that in presence of the moisture of the air, or of a small quantity of added water, the thionylamines are converted into compounds of the amines with sulphur dioxide. Those of the aromatic series usually consist of two molecules of the original amine with one molecule of sulphur dioxide. The first few members of the fatty series form compounds consisting of equal molecules of the amine and sulphur dioxide, and the higher members appear capable of forming both classes of compounds.

During the Easter vacation the Port Erin Biological station has been full. The Liverpool Marine Biological Committee organised a dredging expedition, and the steamer *Lady Loch* was hired for some days, during which a trip was made to the deep water lying west of the Isle of Man, and the shallower ground round the Calf Island and off Spanish Head was also explored. On one of the days the calm sea and low tide enabled the wonderful caves near Spanish Head to be visited in a boat from the steamer. The exposed sides, parts of the roof, and as far down as can be seen in the clear water, are closely covered with rounded red ascidians adhering together in masses, black and white sponges, and tufts of *Tubularia*, forming altogether a most striking sight. The sponges are mostly *Pachymatisma johnstoni*, and the ascidians are Alder's *Polycarpa glomerata*, a somewhat variable species solitary specimens of which have been sometimes referred to *Styela rustica* (a species which probably does not occur at all in British seas). Amongst the more noteworthy animals obtained on these recent dredging expeditions were *Virgularia mirabilis*, *Corynactis viridis*, *Depastrum cyathiforme*, *Amphiura chiajii*, *Palmipes placenta*, *Porania pulvillus*, *Stichaster roseus*, *Luidia ciliaris*, *Brissopsis lyrifera*, *Thyone fusus* and *T. raphanus*, *Hyalinœcia tubicola*, *Calocaris macandrewœ*, *Pasiphœa sivado*, *Xantho tuberculatus*, *Ebalia tuberosa* and *E. tumefacta*, *Hippolyte spinus*, a new species of *Metopa*, *Munida* sp., *Isocardia cor*, *Lyonsia norvegica*, *Spirialis retroversus*, *Fissurella grœca*, *Capulus hungaricus*, *Pleurobranchus plumula*, *Lamellaria perspicua*, *Dendronotus arborescens*, *Tritonia hombergi*, *Eolis tricolor*, *Eolis angulata*, *Actœonia corrugata*, *Scaphander lignarius*, and a new species of the compound ascidian *Glossophorum*, allied to *G. humile*, Lahille, but differing in the colour of the colony and also in minute structure. Prof. Brady and Mr. Thompson obtained a number of interesting Copepoda, including a new *Dactylopus*, and a new and very large *Lichomolgus*, which is found inhabiting *Pecten maximus*, just as *L. agilis* inhabits the common cockle. Since the L. M. B. C. Easter dredging party left Port Erin the following have been working at the station:—Prof. M. C. Potter, Prof. F. E. Weiss, Mr. W. J. Beaumont, Mr. E. T. Browne, and Mr. J. H. Vanstone. Another dredging expedition will be organised for the Whitsuntide vacation.

Notes from the Marine Biological Station, Plymouth.—Last week's captures include the rare Polyclad *Prostheceræus vittatus* and Macruran *Gebia stellata*, and a remarkable haul of the Nudibranch *Hero formosa* whose first capture on our southern coasts was recorded a few weeks ago. The investigation of the floating fauna is much impeded by the continued abundance of gelatinous algæ, which clog the meshes of the townets at all depths. The Leptomedusa *Irene pellucida* is still fairly common, and the pelagic larvæ of *Cereanthus* (*arachnactis*) have now reached a high grade of development. The following animals are now breeding:—The Hydroids *Clava multicornis*, *Gonothyrœa Loveni*, *Sertularia pumila* and *Plumularia pinnata*; the Nemertine *Cephalothrix bioculata*; and the Decapod Crustacea *Eupagurus bernhardus* and *Portunus pusillus*.

THE additions to the Zoological Society's Gardens during the past week include a Crowned Gibbon (*Hylobates pileatus*, ♀) from Borneo, presented by Mr. Leicester P. Beaufort; a Bengalese Cat (*Felis bengalensis*) from India, presented by Captain F. Whistler; a White-bellied Hedgehog (*Erinaceus albiventris*) from Somaliland, presented by Mr. H. W. Seton-Karr, F.Z.S.; five Weasels (*Mustela vulgaris*) British, presented by Mr. George Long; a Festive Amazon (*Chrysotis festiva*) from Guiana, presented by Mrs. Hills; a Chinese Lark (*Melanocorypha mongolica*) from China, presented by Mrs. Pollard; two Serin Finches (*Serinus hortulanus*) from south-west Spain, presented by Mr. J. A. Crawford, F.Z.S.; an Undulated Grass Parrakeet (*Melopsittacus undulatus*) from Australia, presented by Mast. W. D. Savory; a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, presented by Mr. E. P. Ramsay; two Hawfinches (*Coccothraustes vulgaris*) British, presented by Mr. A. Klosz; a Magpie Tanager (*Cissopis leveriana*) from south-east Brazil, presented by Mr. H. A. Astlett; two Great Cyclodus (*Cyclodus gigas*) from Australia, presented by Captain Clarke; a Common Viper (*Vipera berus*) British, presented by Mr. Briton Rivière, R.A., F.Z.S.; a Poë Honey-Eater (*Prosthemadera novæ-zealandiæ*) from New Zealand, a Malabar Green Bulbul (*Phyllornis aurifrons*), a Red-eared Bulbul (*Pycnonotus jocosus*) from India, a Cape Coly (*Colius capensis*), two Derbian Zonures (*Zonurus derbianus*) from South Africa, two American Blue Birds (*Sialia wilsoni*) from North America, two Great Eagle Owls (*Bubo maximus*) European, deposited; two Black-necked Swans (*Cygnus nigricollis*, ♂ ♀) from Antarctic America, two Madagascar Love-birds (*Agapornis cana*, ♂ ♀) from Madagascar, a Red-sided Eclectus (*Eclectus pectoralis*, ♂) from New Guinea, purchased; a Red Kangaroo (*Macropus rufus*, ♂) a Great Wallaroo (*Macropus robustus*, ♂), seven Satin Bower Birds (*Ptilonorhynchus violaceus*) from Australia, two Maugés Dasyures [(*Dasyurus maugæi*, ♂ ♂), a King Parrakeet (*Aprosmictus scapulatus*), two Diamond Snakes (*Morelia spilotes*), a Water Lizard (*Physignathus lesueuri*) from New South Wales, received in exchange.

OUR ASTRONOMICAL COLUMN.

SOUTH POLAR CAP OF MARS.—During the opposition of Mars in 1892 Prof. George Comstock made a series of determinations of the position angles of the south polar cap of Mars, of its angular extent, and of its polar and equatorial diameter. In the first-mentioned measurements he placed the micrometer thread tangent to the planet's disc, and so rotated it that it was symmetrically situated about the point of tangency; one observation included five settings of this kind, with a determination of the parallel from a neighbouring star, and for the majority of the observations these measurements were made both with telescope east and west. The angular dimensions of the caps were measured by placing the thread tangential to the disc of the planet at the extremities of the cap. The coordinates of the centre of the spot, where θ represents the areographical longitude and λ the south polar distance, together with the diameter of the cap and the adopted corrections to the position angle of the axis of Mars as given by Marth's ephemeris, may be gathered from the following table:—

1892.	Diam. of Cap.	λ	θ	Ephem.
	°	°	°	°
July 26	44	0·47	341	−2·26
Aug. 18	35	2·95	311	−3·06
Sept. 19	22	2·95	336	−2·66

Prof. Campbell finds the correction to the position angles, as given by Marth's ephemeris as −0°·16, while Prof. Hall's correction amounts to +1°·24, both of which vary considerably from the values given above. These differences, as Prof. Comstock points out, may arise from the systematic errors affecting the three methods employed.

The measures of the diameter as made at opposition were as follows:—

Date.	Eq. diam.	Polar diam.
	″	″
Aug. 5	26·06	25·19
,, 6	25·80	25·36
,, 7	26·25	25·67

THE BRIGHTNESS OF THE MAJOR AND MINOR PLANETS.—The latest publication issued from the Astrophysical Observatory at Potsdam (No. 30) contains all Dr. G. Müller's determinations of the brightnesses of both the major and some of the minor planets. These observations extend over a period of about eight years, but the majority were made during the years 1883–85. The first chapter is devoted to a tabulation of the different stars used throughout the work for purposes of comparison. In the second are brought together all the planetary observations, while the third consists of a discussion of the whole number of observations, each planet being independently treated. To state briefly some of the results that these determinations have brought to light we may say: (*a*) That with the exception of the planets Jupiter, Uranus, and Neptune, the variations in brightness are found to be directly dependent on the phase differences, which can be plotted out in simple curves. (*b*) That from the observations of each planet the "Lichtschwankungen" accord with no theory, and that near opposition the variations in brightness are found to be larger than those which should be the case as regards the theoretical values. (*c*) The form of the light curves, when one expresses the brightnesses in stellar magnitudes, approaches very nearly, except in the case of Venus, a straight line, and the variations in magnitude are also very nearly proportional to the corresponding phase-differences. (*d*) The observations give no indication of the dependency of the "Lichtstärke" on the rotation of the planets. And lastly (*e*) that by taking series of observations of the largest planets, obtaining the mean values from different years, differences are found which, as Dr. Müller says, cannot be due to the inaccuracy of the measures or to the fact that the same instruments were not always used. The following table shows clearly the relative brightnesses that result from the above determinations:—

Name of Planet.	Brightness. Distance 1.	App. radius. Distance 1.	Reduced Brightness.	Relative Albedo.	Zöllner's Albedo.
		″			
Mercury	−0·003	3·23	−0·808	0·64	0·43
Venus	−4·004	8·78	−2·638	3·44	2·33
Mars	−1·297	4·68	−1·297	1·00	1·00
Jupiter	−8·932	94·23	−2·412	2·79	2·34
Saturn	−8·685	77·63	−2·586	3·28	1·87
Uranus	−6·858	36·67	−2·388	2·73	2·40
Neptune	−7·053	43·15	−2·229	2·36	1·74

METEOR SHOWERS.—Of the important meteor showers which occur during the present month that which occurs on the sixth exceeds all others in brilliancy. On the evening before and after this date there are also two other showers, but they are much fainter. The positions of the radiant points are, according to Mr. Denning:—

Date.	Radiant. R.A.	Radiant. Decl.	Meteors.
		°	
May 5	254	−21	Slowish
,, 6	338	−2	Swift; streaks
,, 7	224	+7	Slow; bright

ASTRONOMY POPULARISED IN AMERICA.—There seems to be no doubt that the interest taken in astronomy in America is rapidly on the increase, and the demands for large telescopes there have played no small part in helping to stir up in many minds the desire for enlightenment in this fascinating science. Increase in the number of students and amateurs, and rapidly growing demands for small telescopes are signs that cannot be misconstrued, indicating as they do the vast interest that even to-day is shown in the oldest of sciences. To satisfy and further these favourable omens, or in other words to bring together those who can instruct into close relations with those who are to be instructed, the editors of *Astronomy and Astrophysics* propose, assuming they get a sufficient number of subscribers, to issue a monthly publication entitled "Popular Astronomy." The idea of this project is that it should serve as a guide for self-instruction, and supply a medium for queries and answers for methods of work, facts, books, &c. They propose to commence with a series of topics for observation, the stars, moon, planets, &c., assuming that the readers are supplied only with an opera glass or small telescope. It is to be in no sense professional, "except to be accurate in statement of fact and principle without being technical in terms." The first number can be ready by September of this year if the subscribers are forthcoming.

OPTICAL TESTS FOR OBJECTIVES.—In a small pamphlet entitled "Optische Untersuchung von Objectiven," by Dr. Ludwig Mach of Prague, the contents of which have appeared in the *Photographischer Rundschau*, the writer describes a very simple means of obtaining photographs of objectives showing defects in the glass. After first referring shortly to the methods adopted by Schröder, Alvan Clark, &c., giving some excellent small photographs of some of the results obtained by these means, he decribes his method of making small optical errors visible. He casts, by means of an achromatic lens, an image of the sun on a screen in which is a small hole. Behind this screen, at some distance from it, he places the object glass to be tested, together with the camera at its focus, and it is found that in all places where the object glass is not perfect a system of interference marks or rings is formed. Experimenting with an object glass of 10·2 cm. aperture and 143 cm. focal length, by Sir Howard Grubb, the writer shows a photograph taken after this means.

PHOTOGRAPH OF A BOLID.—Although on fine nights many telescopes carrying with them photographic plates are turned towards the starry heavens for special objects, none, except a very few exceptions, have had the good luck to record the passage of a bright meteor. M. Lewis, at Ausonia (Connecticut) seems to have been very fortunate in this respect (*Bulletin Astronomique*, tome x., March), for on January 13 of this year, while photographing the comet Holmes, a very bright meteor crossed the field of view. An examination of the plate showed that the trail commenced at about 1h. 38m. R.A., and + 33° 40′ declination, terminating at 0h. 8m. R.A., and + 32° 12′ declination. Under the microscope he says that the centre of the trail is crossed by a very dark axis, clearly defined, while the other part is bounded by fringes of very irregular forms, indicating that fragments of matter had been detached from the meteorite: signs of rotary movement during its passage before the sensitised plate were also visible. For orbit determinations, photographs such as these, if they could be more often obtained, would be very valuable, for one could then fix the different points of the trajectory with far greater accuracy than is now done by the necessarily very approximate method of naked eye estimations.

GEOGRAPHICAL NOTES.

AN amusing instance of newspaper science occurred in a morning paper last week. A note on the salinity of the North Pacific, published in this column (vol. xlvii. p. 590), was reproduced without acknowledgment, but with annotations. After the quotation, "a tongue of considerably fresher water stretches nearly across the ocean about 10° N." came the interpolation, "caused no doubt by the dilution of the sea by the melting snow and ice of the northern regions," a far-fetched hypothesis, which ignores the rainy belt of calms. A worse error was to say that the curves of equal salinity "run through Behring Strait," when the original said Bering Sea. The use of a map would probably have prevented the blunders.

THE *Mouvement Géographique* publishes a useful *résumé* with route-maps and portraits of the officers of the various expeditions of the Katanga Company from May, 1890, to April, 1893. In July, 1890, the expedition of M. A. Delcommune left Europe for the Congo, went by the Lomami, discovered Lake Kassali, and reached Bunkeia, in Katanga on October 6, 1891. This expedition spent a year in exploring the upper Lualaba and the western side of Lake Tanganyika, then descended the Lukuga, crossed the Congo basin in a west-by-north direction to Lusambo, and arrived in Brussels on April 15, 1893. An expedition under Le Marinel left Lusambo on December 23, 1890, reached Bunkeia on April 18, 1891, and after taking possession of Katanga, returned to Lusambo in August of the same year. On July 4, 1891, Captain Stairs left the east coast, and travelling by Lake Tanganyika reached Bunkeia in December, but the leader died on the Zambesi on his way home on June 8, 1892. In September, 1891, Captain Bia's party left Stanley Pool, ascended the Sankuru, discovered Lakes Kabele and Kabire, near the Lualaba, and reached Bunkeia in January, 1892. Thence in June they reached Lake Bangweola, and after Captain Bia's death, Lieutenant Francqui led the expedition through the upper regions of the Lualaba, and in January, 1893, joined Delcommune at Lusambo, returning with him to Europe. The discoveries made by these four expeditions are of great importance; they fill in much of the detail of the Congo basin hitherto very lightly sketched on the maps.

A RUMOUR has been current that Dr. Nansen's polar expedition is likely to collapse at the last moment for lack of funds; but it is satisfactory to learn that this is not the case. The *Fram* is practically ready for sea, and the party will embark in the month of June, as originally intended.

THE recent advance in Arctic navigation is strikingly shown in the announcement by a Norwegian firm of a pleasure-trip to Spitzbergen, planned for this summer, with a vessel strengthened for ice-work and fitted with every comfort.

MM. FOUREAU AND MERY have during the past year carried out some important journeys in the Sahara. They have succeeded in reaching the country of the Tuaregs, which has not been visited by Europeans since the Flatters' mission was massacred in 1881, and they have induced the chiefs to acknowledge French protection. The French officials are diligently extending the cultivable area of the oases in the northern Sahara by sinking artesian wells and securing artificial irrigation.

THE USE OF HISTORY IN TEACHING MATHEMATICS.[1]

I HAVE ventured to make some suggestions to this Association as to the use of history in teaching mathematics, and the restrictions and limitations under which it may be advantageously employed. It will be perhaps the most convenient course to begin with the restrictions and limitations.

The three most important of these are:—

(1) The history of mathematics should be strictly auxiliary and subordinate to mathematical teaching.

(2) Only those portions should be dealt with which are of real assistance to the learner.

(3) It is not to be made a subject of examination.

Unless these conditions are observed, it is to be feared that the effect of the introduction of new matter for instruction would be injurious rather than beneficial. The ordinary schoolboy or schoolgirl now takes in hand quite as many subjects as he or she can satisfactorily study, and nobody wants the number to be increased.

When men look back on their school days, they constantly feel some things they have always remembered and often applied came to them from their masters not as part of the regular course or as included in the work done for examination. It is just this outside illustrative position that I propose history should occupy in respect to mathematics. I want at the outset to free myself from any imputation of desiring to add one grain's weight to the heavy burden boys and girls have to bear in these days of competitive examination.

Coming now to the main question, which is in what ways history makes mathematical study easier, clearer, or more interesting, it may first of all be remarked that it gives us stereoscopic views instead of pictures and diagrams. A particular subject may be looked at from many sides, each aspect suggesting a different mode of treatment. Thus, although we do not want to go back to the method in Whewell's Mechanical Euclid, where the main truths of elementary statics were all derived from the fundamental axiom that a ruler would balance if its middle point were supported; it is yet a good thing for the pupil to know that such a method was successfully adopted. We do not want in arithmetic to go back to the old-fashioned rules of single and double false position, but the student is all the better for knowing what they were, and what could be effected by their means. Possibly some of us might really like to go back to the proof of Euclid I. 47 in the "Vija Ganita," depending only on the almost obvious truth that triangles of the same shape have their sides proportional, but at all events a student should know about this proof, even if he were to be warned of the objections to using it.

In some instances there is a further direct advantage in recalling old methods that are now superseded. Though the change

[1] Abstract of a paper by Mr. G. Heppel, read before the Association for the Improvement of Geometrical Teaching.

has been wisely made, yet it may happen that some important particulars have become comparatively obscured under the new treatment, that were in full light when the older plan was in vogue. Since Harriot introduced into England the grand and powerful improvement of making letters of the alphabet stand for unknown quantities, school boys have been for the most part regularly trained to look on algebra as a game of hide and seek, where x is concealed under conditions, and has to be dragged out into the light. The idea of some undetermined radix of a scale of notation, which was the very essence of the algebra of Stifel and Stevin, has not been brought prominently before them. It may be of interest to give four successive stages by which a process of multiplication in algebra has arrived at its present form. The first, originated by Stifel and adopted by Recorde, made use of very strange signs with very odd names. In the product, beginning from the right, the first term was called the *absolute*, the second the *root*, the third the *square*, the fourth the *cube*, the fifth the *zenzizenzike*, and the sixth the *sursolide*. In the second stage, Stevin's notation, adopted by Briggs, is self-explanatory. The third system is Vieta's, adopted by Harriot.

\end{array}
$$

As another example, a boy can use logarithms and understand what they are, directly he has mastered the law of indices, but in order to calculate them he imagines that he must know the Binomial and Exponential Theorems. Surely it would aid him to comprehend the relations of logarithms to numbers, if he knew that they were originally calculated when the Binomial and Exponential Theorems were unknown, and if he were given some slight sketch of the means by which they were then determined.

In the *Daily News* of December 16, 1892, a verse was quoted as being often found written in a schoolboy's Euclid or Algebra:—

> "If there should be another flood,
> Hither for refuge fly,
> Were the whole world to be submerged,
> This book would still be dry."

The schoolboy's charge of dryness must be met by showing him how the progress of the arithmetic, geometry, algebra, and trigonometry that he is learning has gone on in answer to the needs that men have felt, and the desires they have formed.

There have been periods in which men, under the influence of some widely-spread motive, have called for the aid of the theorists to help them on their course, and the endeavour to supply the great want of the time has brought about a great advance in theoretical knowledge. As we look at the course of these great movements, we find that it is the practical men that supply the stimulus to exertion, that set the few thinking for the advantage of the many. Three instances of these great wants of life—one of them now dead, the other two in ever-increasing life and vigour, stand out prominently beyond the rest—astrology, commerce, and navigation. The influence of astrology extended over such a vast period of time that we cannot trace its progress step by step from the ancient Chaldeans to the Doctor Dee of the reign of Elizabeth, who was the last eminent English mathematician of the astrological sort, and at the same time one of the great promoters of mathematics in its more modern applications. We can see, however, what has been left to us as the result of the attention that was paid to astrology. The works of Bhascara, himself an astrologer, show the extent to which the Indian arithmetic and algebra had gone, and what stock was in hand to be turned to the new purpose of facilitating European commerce. We had also from these ancient scholars the elements of trigonometry and tables of sines and cosines.

The old astrologers were maintained and were enabled to carry on their researches by the wealth of princes: Alphonso, King of Castile; Frederick II., Emperor of Germany; Matthias Corvinus, King of Hungary, are instances of monarchs who had astrologers in their train, filling recognised positions in their courts. Some of these were men of real learning; others, like Galeotti, introduced with the romance writer's licence as to place and time in Scott's "Quentin Durward," and Lilly, who successfully deluded the Parliamentary leaders in the Civil War, were not much better than quacks.

When we leave the astrological age and proceed to the commercial, the history is much more complete and more interesting. The whole story of the introduction of Indian arithmetic into Europe by means of the Arabians, first as the result of the Moorish conquests in Spain, and then, after a long interval, as a result of the commercial enterprise of Italy, is full of romantic interest. It is curious to notice how strongly the commercial element comes out in the algebra of Mahommed ben Musa. It is all about questions of money, partnerships, and legacies. When the practical objects for which mathematics were studied became different, there was a corresponding alteration in the mode by which such researches were encouraged and maintained. There still remained the patronage of great princes and nobles, but a new class of promoters arose among the great merchants and trading communities. A great wave of public enthusiasm seems to have borne along with it all classes of society, engaging them in the advancement of the new learning. Benedetti held the office of mathematician to the Duke of Savoy, with a good salary; Torricelli was mathematician to the Duke of Tuscany; Harriot received £300 a year regularly from the Earl of Northumberland, and while his noble patron was for fifteen years in prison for complicity with some of the ambitious plots of his friend Sir Walter Raleigh, Harriot, Hues, and Warner bore him company, and were generally spoken of as the Earl's three magi. As showing the interest taken by the traders of great cities, it may be noticed that some of the most important treatises of the time were written at the instigation of the merchants of Florence, and published at their expense. In our own country, the first English translation of Euclid was made by a citizen of London. Recorde dedicates the first English algebra to the company of Merchant Adventurers trading to Muscovia.

Important advances in mathematics were made by the professors at the college in London, founded by Sir Thomas Gresham. This feeling among the trading classes produced results in Italy which Libri tells us were unparalleled in any previous time. We all know of the Floral Games of Toulouse, and the athletic contests of the Greeks at Olympia and Corinth. But Libri tells us that just this interest, just this popular excitement was felt in Italy when Ferrari or Bombelli had made a step in advance in the solution of cubic and biquadratic equations. There were public challenges to contests of skill, proclamations by heralds, wagers to be decided. There is a collection of answers given by Tartaglia to questions submitted to him for solution by men from all ranks in society, princes, monks, doctors, ambassadors, professors, architects, and merchants, and a large proportion of them had to do with cubic and biquadratic equations. It may seem rather strange that this particular portion of Algebra should have excited so much interest, but it must be remembered that it is not possible to determine beforehand what researches into abstract truth will afterwards lead to the greatest practical benefits. There was a widespread belief that the new powers of calculation would bring about material advantage.

I trust that I may be pardoned for thus bringing forward matters which are no doubt very familiar to most of the members of this Association; but the object has been to give a sample of the kind of facts that would be likely to appeal to the minds of young learners, and to attach some human interest to the abstract subjects they are studying. This human interest is to be found in the history of navigation not less than in that of commerce. The relation between the commercial impulse and the navigation impulse was not exactly one of succession. The former was the earlier, then the two for a time went on together, and afterwards the latter was supreme as a ruling motive for promoting mathematics.

The two great problems in navigation were first, if you knew where you were, to find how you could best get somewhere else; and secondly, if you did not know where you were, to find this out by astronomical observation. The solution of the first was mainly dependent on maps and charts, and consequently for a long time men were hard at work making these for the use of sailors. The first great promoter of this work in modern times was Prince Henry of Portugal, called the Navigator, and after his death in 1460 to the close of the century, Portugal, eagerly engaged in the exploration of the coast of Africa, continued to be the great chart-producing country. Later on it was to the Netherlands that we were principally indebted for improvements in this direction, and in the long list of those thus engaged a prominent place is taken by Stevin. Mercator's projection is so called from Kauffman, who invented it in 1566, but did not clearly show the principles on which it is founded, a task that was afterwards accomplished by an Englishman, Edward Wright, whose great services to science have been but scantily recognised.

The second great problem—to find out where you are by astronomical observation—was a pressing question in the sixteenth and seventeenth centuries. The chief instrument the Elizabethan mariner had at his command was the astrolabe. This was made in very various forms. For use at sea, of course the simplest form was chosen. There is a plate in Hutton's Mathematical Dictionary of one, consisting of a graduated circle held up by a ring, and so keeping a vertical position by its own weight, furnished with an arm and two sights, by which the altitude of the sun, moon, or stars could be estimated. The astrolabes in use on land were fitted up with much greater refinement.

An instrument perhaps more frequently used, easier to work with than the astrolabe, but less accurate, was called the cross-staff or fore-staff. It was composed of a graduated wooden rod, about three feet long, with cross pieces sliding along it of different heights, and the angle was observed in the same way that a volunteer uses the sights on his rifle. This fore-staff could be applied to roughly determine the distance between two stars.

To determine with any accuracy a ship's place at sea, three things are requisite. First, a theory that is true and workable as far as it goes; secondly, means of observation; thirdly, means of calculation. A defect in any one of these requisites renders comparative excellence in the other two o small use. Now, the mariners of Drake's time had scanty theoretical knowledge, poor instruments, and very deficient means of calculation. They could, in a rough fashion, find out in about what latitude they were; the longitude remained a mystery.

It was at the beginning of the seventeenth century that the first great improvement took place. The invention of logarithms, by Napier, placed the calculating power at one bound far in advance of either the theoretical knowledge or the means of observation. His system, further developed by Briggs, the Gresham professor, so completely supplied the want previously existing, that any improvements made between then and the present time are mere matters of detail.

The improvements in theory and in instruments went on gradually and together. Tycho Brahe did much to advance the efficiency of instruments, and every step in this direction gave the means of correcting or developing previous defective theory, and each theoretical advance suggested or rendered possible some new instrument of observation. It is no proper part of my subject to trace the steps of this progress. It is sufficient to say that now the shipmaster, often a man of no great scientific attainments, generally accustomed to work by rules, the reasons for which he does not know, has in his cabin a chronometer and a book of navigation tables, which represent in a material form the genius and the toil of the master minds that have arisen during the centuries of the past.

In the application of pure mathematics to navigation, as well as to many other purposes, it is curious to notice the changes in the relations between graphic methods and calculation methods. At first the former greatly predominated. The quantities of straight lines and curves engraved on Drake's astrolabe, the profusion of scales on old sun dials, that but few thoroughly understand, were originally intended and were accepted as the most simple means of determining practical problems. They gradually gave place to numerical calculation, but not very quickly. Fifty years ago a boy's training in the elements of navigation was conducted far more on the lines of geometrical construction than it is at present. In quite recent times there has been a revival of graphic methods in a somewhat different aspect. Besides the value they have always had for illustration and explanation, it has been seen that there is a special field for them in cases where calculation would be long and troublesome, and this special field is being clearly marked off.

The correspondence between the practical aims of men and the progress of theoretical knowledge and of means of calculation does not stop with navigation. In recent times the need for more powerful or more exact machinery, the employment of steam and electricity, our increased knowledge of what is meant by heat and light have had the effect of demanding fresh advances in mathematical methods; or, perhaps, more exactly of selecting from the mass of abstract truth acquired for its own sake the particular portion suited to the special purpose. These influences have had, however, nothing to do with the schoolboy's elementary programme, and are, therefore, outside the immediate subject of this paper.

In conclusion, I would urge that if there is any sound foundation for the views that have been expressed, we ought not in England to be without some elementary primer of the History of Mathematics.

FOGS AND HORTICULTURE.

PROF F. W. OLIVER'S second report on the effects of urban fog upon cultivated plants has been presented to the scientific committee of the Royal Horticultural Society, and is now printed in the Society's Journal. The following is the passage in which he deals with possible remedial measures:—

There is very little of what I can say likely to be consoling to the horticulturist. We must recollect that in the employment of measures directed towards mitigating the injuries incident to fog, two factors—the presence of poisons in the atmosphere and the reduction of light—have to be considered. To counteract these the urban cultivator is asked to construct air-tight houses, with definite openings where the admitted air can be filtered; whilst to compensate for the loss of light due to the absorption which the rays undergo in traversing a stratum of dense fog, he must provide a generous installation of electric light. Without doubt, the entire preservation of vegetation in foggy weather is only a matter of *£ s. d.* But it is for the cultivator to sit down and count the cost. Representative growers agree in advising me that although horticulture, under these conditions, would be very interesting from a scientific point of view, it would hardly be commercially desirable. The necessity for the reconstruction of glass-houses upon valuable urban land must of necessity suggest to the horticulturist the alternative of decamping into the country, where the cultural conditions are more favourable. The enhanced value of urban sites has, apart from other inducements, no doubt been a factor in determining an increasing number of growers to settle well outside the suburbs. If, then, any idea of reconstruction is raised, it would in all probability prove to be the last straw. Considerations of this sort lead me, in making a few remarks upon cultural precautions, to limit my suggestions to such as are possible of realisation—things being as they are.

If we could eliminate atmospheric contamination, I do not think the reduction of light alone would be a very serious cause of complaint. Now and then it might be so to some extent, though it would hardly be a grievance of the first magnitude. It is when we have superadded aërial contamination that the mischief is done. Many very common injuries to flowers—injuries which impress the cultivator and catch his attention—have no casual relation with diminished illumination. The inflorescences of rhododendrons, which become so characteristically glued up in their bud-scales and fail to open, will expand perfectly in total darkness. So also will the flower-buds of most orchids. Since, however, the application of artificial light, in a manner likely to be effective, would be an unduly heavy burden on the grower, we will dismiss this aspect of the question, and proceed to discuss whether atmospheric contamination can be cheaply remedied.

And, first of all, can fog be neutralised or absorbed after it has entered a plant house? I have experimented with several things, but my results do not justify me in basing any recommendations upon them. The sluicing or syringing of liquid chemicals about a house has little to recommend it, even when attended with some success. To solids the objection is not so great. But I have not found that carbonate of ammonia, for instance, exerts any noticeably beneficial action as a neutraliser of the acid vapour of fog. But fog is a complex product, and anything which might neutralise one constituent would probably leave the others free to do their damage. I have never felt that anything could be done inside the house towards mitigating fog except the taking of certain precautions as regards watering and heating. And I am of this opinion still.

The scope of this report does not extend to a discussion of the big question of the abolition of fog. Even the most sanguine of the present generation can hardly hope to enjoy any abatement of the fog-nuisance. So that I shall be more practically discharging my mission in discussing how fogs may be excluded from plant-houses than in attacking the greater problem. Stoves, within certain limits, can be covered in with sheets of canvas, and this has been tried with encouraging results. I first heard of this method being systematically and successfully applied from Mr. C. Davies, of the Mote Park Gardens, Maidstone. Even the fogs of limited duration which are experienced there are sufficient to destroy the blossoms of a whole houseful of orchids. But they have been successfully combated by covering in the house with canvas sheets. Elsewhere I have seen this done, sometimes at my suggestion, with beneficial results. Still, at the best, it is but an expedient. Immunity obtained in this way is only partial. Severe fogs of short duration, or longer ones of only moderate density, may be filtered through canvas, so that the damage caused is lessened; but a persistent dense fog generally prevails in the end.

If plant-houses were constructed rather less leaky than is the case at present, something definite could no doubt be done towards filtering the air. I confess to holding serious doubts as to whether the admission of air to plant-houses, as in vogue just now, is based on sound physiological principles—and this quite apart from the fog-nuisance. During the course of my inquiries into fog, a device for ventilating conservatories—the "patent fog-annihilator" of Mr. Charles Toope—came prominently under my notice; and as I have been frequently asked what I think of it, I will take this opportunity of stating what I know. The system is as follows: A number of boxes, situated on the floor under the staging, communicate directly with the exterior by means of aperatures which can be readily closed if desirable. These boxes contain several open-work trays, upon which sticks of charcoal are loosely placed. The air entering a box from outside is led through these trays, coming into close contact with the charcoal. As the air leaves the box it impinges upon the hot-water pipes, and is thus warmed before it reaches the plants in cultivation. The entrance of air is promoted by simple contrivances known as "exhaust-caps" placed on or near the ridge of the house. These caps are so constructed that practically, under all conditions, an out-draught of air obtains. Should the draught be too great, it can be regulated by means of valves. By this system a constant circulation of air throughout the house is brought about. The air enters the charcoal-box at once from outside. It passes through this and is warmed by the hot-water system of the house, and ultimately escapes by means of the "exhaust-caps." Excepting for the apertures mentioned the house is air-tight. It is by means of the charcoal that Mr. Toope claims that the air admitted is purified. As the air circulates between the sticks of charcoal it gives up the products of coal-combustion with which it may be contaminated, as in foggy weather.

Charcoal undoubtedly possesses remarkable properties as an absorbent, and Mr. Toope is by no means the first to call attention to its properties in this respect. Forty years ago the chemist Stenhouse[1] made observations on these properties, and it may not be without interest to call attention to what he said about it. In the paper referred to, Stenhouse describes and illustrates the remarkable property of charcoal as an absorbent and oxidiser of the products of decomposition of organic matter. He describes how the carcases of dogs were kept covered with a thin layer of powdered charcoal—but otherwise exposed—without any nuisance arising therefrom. He adds that he has devised a respirator on this principle, to be used in districts smitten with cholera or yellow fever. He found, further, that with such a respirator he could breathe with impunity air containing large amounts of ammonia, sulphurrtted hydrogen, and other hurtful gases. Finally, he suggested the application of charcoal for purifying the air of houses located in infected districts—all air admitted to be passed through thin canvas bags containining crushed charcoal. Were such precautions taken, many regions at that time fatal to Europeans could be, he was sanguine, dwelt in with impunity.

In a later paper[2] Stenhouse describes his experiments, showing how the absorbent property of charcoal could be greatly increased. From this paper I venture to make the following extract, as charcoal seems to have fallen into desuetude as an absorbent:—

"The lighter kinds of wood charcoal, owing to the nine volumes of oxygen gas contained in their pores, possess a considerable power of oxidising the greater number of easily alterable gases and vapours. The absorbent power of charcoal is comparatively much greater than its capacity for inducing chemical combination. In this respect charcoal presents a remarkable contrast to spongy platinum, which, though inferior as an absorbent for some gaseous substances—such, for instance, as ammonia, of which spongy platinum absorbs only thirty volumes, while charcoal absorbs ninety—is, nevertheless, immensely more effective both as an oxidiser and as a promoter of chemical combination generally. As it is desirable, for some purposes, while retaining the absorbent power of charcoal unimpaired, to increase its oxidating influences, it struck me that this important object might be easily effected by combining the charcoal with minutely divided platinum. In this way a combination is produced to which I have given the name of platinised charcoal, which possesses the good properties of both of its constituents. In order to platinise charcoal, nothing more is necessary than to boil the charcoal, either in coarse powder or in large pieces, in a solution of bichloride of platinum, and when the charcoal has become thoroughly impregnated with the platinum, which seldom requires more than ten minutes or a quarter of an hoar, to heat it to redness in a closed vessel—a capacious platinum crucible being very well adapted for this purpose. When 150 grains of charcoal were impregnated with nine grains of platinum, by the process just described, the charcoal was found to have undergone no change in its external appearance, though its properties had been very essentially altered. . . . I find that two per cent. of platinum is sufficient

1 J. Stenhouse, "Ueb. die entfärbenden und disinficirenden Eigenschaften der Holzkohle, nebst Beschreibung eines Kohle-Respirators zur Reinigung der Luft durch Filtration," *Annalen der Chemie und Pharmacie*, Bd. xc. 1854, p. 186.

2 J. Stenhouse, "On Platinised Charcoal," *Journ. Chem. Soc.* viii. 1856, p. 105.

to platinise charcoal for most purposes. Charcoal containing this small amount of platinum causes a mixture of oxygen and hydrogen to combine perfectly in about a quarter of an hour, and this is the strength of platinised charcoal that seems best adapted for charcoal disinfectant respirators . . . . Platinised charcoal seems likely to admit of various useful applications; one of the most obvious of these is its excellent adaptability to air-filters and respirators for disinfectant purposes." So much for the properties of charcoal. My colleague, Prof. Corfield, of University College, assures me that "charcoal is now very little used for the purification of foul air. It was formerly employed in sewer ventilation, but it was found that it soon became damp and was then useless.

I was anxious to test Mr. Toope's application, and to see how far the sulphurous acid of fog might be absorbed as the foggy air passed through the charcoal trays. Mr. Toope, therefore, at my request, furnished me with a sample box, so arranged that I could aspirate air throught it. I was frequently in the habit of aspirating fog through 25 c.c. of potassium permanganate of such strength that the aspiration of $2\frac{1}{2}$ to 3 cubic feet of an ordinary fog would decolorise the solution, whilst $1\frac{1}{2}$ to 2 cubic feet sufficed in the case of very severe fogs. I have repeatedly aspirated air, in all sorts of foggy weather, through the charcoal box. But even in the most severe instances I have never noticed anything more than a slight discoloration of the permanganate after the passage of as much as 25 cubic feet. I have also placed the box in a chamber into which an atmosphere of strong sulphurous acid was introduced—an atmosphere of which $\frac{1}{10}$ cubic foot sufficed to entirely decolorise the permanganate. When drawn through the charcoal, however, 3 cubic feet could be drawn without perceptibly affecting the colour of the fluid. When kept in an atmosphere of strong sulphurous acid the charcoal becomes in time charged, and, for the time being, incapable of further absorption. In this charged condition I left the box for some eight or ten weeks, and found that by the expiration of that time it was as good an absorber as ever. With ordinary fogs there seems little fear of anything of this kind happening; nor have I observed any tendency in the charcoal to get choked in this way in long spells of foggy weather. That other impurities are also absorbed I have no proof, though I consider it most probable.

In order to demonstrate the advantages of his system to horticulturists, Mr. Toope has constructed a small conservatory at his offices in Stepney. Here he cultivates, in an unfavourable atmospheric environment, a collection of orchids and other stove plants. The results I regard as distinctly favourable to his system, though they were not by any means convincing. This arose, not necessarily, from any defect in the filtering apparatus, but rather from faulty cultural methods. Mr. Toope is a busy man, and the charge of his plants falls to the lot of others. Many plants very sensitive to atmospheric impurities, which he obtained at my suggestion, received a severe check in transit before they reached him. Others, again, which he raised from seed for observation were liable to neglect from time to time. So that a casual visitor unacquainted with the facts might easily have carried away an unfavourable impression of the utility of the system. But, taking everything into consideration, I incline to take a distinctly favourable view of charcoal as a filter for contaminated air—so much so that I believe it might be adopted with advantage by our urban cultivators. The charcoal undoubtedly absorbs a very large percentage of the sulphurous acid, and this can only have a beneficial result. The adoption of the system to old plant-houses does not involve any very serious reconstruction. The charcoal-boxes and exhaust-caps are easily fixed; whilst it is only very old and leaky houses that cannot be rendered reasonably airtight. In this way the toxic action of fog will, I am confident, be mitigated to an appreciable extent.

As regards cultural precautions to be observed in foggy weather, experience indicates that a low temperature and a moist atmosphere are conducive to the well-being of the plants, though they, of course, afford no absolute protection. This aspect of the question has been clearly put in the following note from the *Gardeners' Chronicle* by Mr. Thiselton-Dyer, which I venture to quote *in extenso*:—

"The Kew practice of keeping the winter temperature of the houses as low as we dare is based on the result of practical experience. I do not dogmatise for other people who want to solve their own problems, and find out what is best for their particular requirements for themselves. But, as Mr. Henslow has pointed out, the theory of the subject has been stated clearly by Lindley; and it may not be amiss to quote a few words from his classical 'Theory and Practice of Horticulture' on the subject.

"The point of the whole matter is that in winter, with a low external temperature and nocturnal radiation, it is practically impossible, in a large glasshouse, to keep the internal atmosphere humid with a high temperature. I quote from Lindley, p. 207:—

"'Another source of dryness is the coldness of the glass roof, especially in cold weather, when its temperature is lowered by the external air, in consequence of which the moisture of the artificial atmosphere is precipitated upon the inside of the glass, whence it runs down in the form of "drip."'

"Again, 'It is evident that the mode of preventing this drying of the air by the cold surface of a glass roof will be either by raising the temperature of the glass, which can only be effected by drawing a covering of some kind over our houses at night, so as to intercept radiation, or by double glass sashes; or else by keeping the temperature of the air as low as possible, consistently with the safety of the plants, and so diminishing the difference between the temperature of the external and internal air.'

"In large glasshouses it is obviously impracticable to adopt the expedients which Lindley suggests. The only alternative is to do what we do at Kew—lower the temperature as much as possible, and so secure the highest possible relative humidity, with the double result of keeping the plants at rest and of checking their desiccation."

I hope shortly to issue a third report dealing with the fog question from its purely local aspect, including lists of plants which suffer and the area around the metropolis to which these special injuries are observed.

In due time I shall prepare a very detailed report or monograph, illustrated from the large series of drawings which I have accumulated. It will only be in such a detailed monograph that I shall be able to justify many of the statements which occur in the body of this, the second report.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Mr. Pendlebury, of St. John's College, has been reappointed a University Lecturer in Mathematics, for five years, from Lady Day 1893. Prof. Macalister, President of the Anthropological Institute, has given three lectures this term on Physical Anthropology as follows: April 27, "The Races of Australia;" April 29, "The Ancient Egyptians;" May 2, "The Prehistoric Races of Britain."

The Professor of Pathology announces a practical course of instruction in bacteriology, to be given during the ensuing long vacation, by Prof. Adami, Dr. A. A. Kanthack, Dr. Wesbrook, and Mr. L. Cobbett.

Mr. J. Y. Buchanan, F.R.S., will deliver the second part of his course of lectures on oceanography at noon on Tuesdays during the present term.

The Smith's Prizes are this year awarded to three mathematicians, who are bracketed, namely, C. E. Cullis, B.A., of Caius, for an essay "On the Motion of Perforated Solids in an Incompressible Liquid"; D. B. Mair, B.A., "On the Continuous Deformation of Surfaces"; and R. H. D. Mayall, B.A., of Sidney, "On Certain Forms of Current Sheets." Mr. Mair and Mr. Mayall were bracketed Second Wranglers, and Mr. Cullis bracketed Seventh Wrangler in the Mathematical Tripos of 1891.

SCIENTIFIC SERIAL.

American Meteorological Journal, April.—Ice columns in gravelly soil, by Prof. C. Abbe. During spring and autumn little slender columns of ice are found at the surface of gravelly soils in moist places after a clear cool night, and the surface layer is found to be raised up an inch or two. Prof. Abbe offers an explanation of the phenomenon, which differs from that given by Leconte and others. The subject is of some importance to agricultural soil physics.—The diurnal variations of barometric pressure, by C. J. Lyons, of the Hawaiian Weather Bureau. The author takes into account the expansion of the air both upwards and laterally, caused by the apparent motion of the sun, and he considers that it is the *lateral* pressure that causes the barometer to rise to a maximum about half way between local sunrise and local maximum of temperature. He states that an advancing area, which is increasing in the temperature of its lower strata, will cause a high barometer area at a considerable distance in front of itself, and that the reverse occurs during the advance of an area which is diminishing in the temperature of its lower strata. The evening maximum he takes to be a reactionary wave from the afternoon minimum.—Recent foreign studies of thunderstorms, by R. de C. Ward. The author has collected the literature of the subject from the time that Mr. G. J. Symons commenced his observations, in 1856, down to the close of 1892, and gives a general summary of the results of each discussion. The present paper refers entirely to Great Britain.—The Chinook wind, by H. M. Ballou. Comparatively little has yet been written about the Chinook wind; its name is derived from that of the tribe of Chinook Indians living near Puget's Sound. During the prevalence of the wind the thermometer often rises from below zero to 40° or 45° in a few hours. It is analogous to the Föhn in Switzerland, and similar winds are reported from various parts of the world. All that is needed to produce them are high and low pressure areas, whereby the air is caused to pass over the mountains, depositing its moisture during the ascent, and descending on the leeward side. The author gives a list of works bearing upon the subject.—The North Atlantic hurricane of December 22, 1892, by E. Hayden. The paper is accompanied by a map showing the great size and severity of the storm. It is estimated that the area embraced was fully four million square miles, and the author considers that this storm is accountable in some degree for the subsequent very cold weather in North America and Europe.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 9.—"Preliminary Account of the Arrangement of the Sympathetic Nervous System, based chiefly on Observations upon Pilo-motor Nerves." I. By J. N. Langley, F.R.S., Fellow of Trinity College, Cambridge. In the cat, the spinal nerves which contain pilo-motor fibres in their nerve-roots, are usually the 4th thoracic to the 3rd lumbar inclusive. The spinal pilo-motor fibres run into the sympathetic trunk, there they become connected with nerve-cells; on leaving the sympathetic chain, they run to their peripheral endings in cranial or spinal nerves. The fibres to the body accompany those dorsal cutaneous branches of the spinal nerves, which supply the skin over and close to the vertebræ. Broadly speaking, the pilo-motor fibres run from the sympathetic chain to the cranial and spinal nerves in the grey rami, but a few fibres may run out in the white rami. Broadly speaking, the fibres issuing from any one ganglion are connected with nerve-cells in that ganglion and with no other sympathetic nerve-cell. In some cases a certain number of such fibres are connected with nerve-cells, not in the ganglion from which they issue, but in the ganglion immediately above or below it. The fibres, before and after they have joined nerve-cells, may be called respectively pre-ganglionic and post-ganglionic. Each ganglion, by its post-ganglionic fibres, supplies, in any one individual, a definite portion of skin. The areas supplied by the ganglia from above downwards, starting with the superior cervical ganglion, are, apart from a variable amount of overlapping, successive areas. The cranial rami of the superior cervical ganglion supply the skin of the dorsal part of the head, except a posterior portion, beginning about 1½ cm. behind the anterior level of the ears; this unaffected region we may call the occipital region. The cervical rami of the superior cervical ganglion supply the skin of the occipital region of the head by fibres running in the great occipital (2nd cervical) nerve, and the skin over the first three or four cervical vertebræ by fibres running in the 3rd cervical nerve. The ganglion stellatum, by its cervical rami, supplies the skin from the 3rd and 4th cervical vertebræ to some point between the spine of the 2nd and 3rd thoracic vertebræ. Often its area extends upwards to join the occipital region. The areas supplied by the post-ganglionic pilo-motor fibres of the 3rd, 4th, 5th, and 6th cervical nerves vary in relative size in different individuals; roughly we may take the 3rd nerve as supplying the skin over the first three and a half vertebræ, and the others as supplying successive strips of about two vertebræ each. In the fore leg region, one, two, or three spinal nerves send no cutaneous branches to the mid-line of the back. These are the 7th and 8th cervical, and the 1st thoracic, nerves. Sometimes the 7th, sometimes the 1st, thoracic has such a cutaneous branch; corresponding to the presence or absence of these cutaneous branches is the presence or absence of pilo-motor fibres in the rami which pass from the ganglion stellatum to the respective nerves. The ganglion stellatum also sends pilo-motor fibres to the first four thoracic nerves. From the 5th thoracic nerve downwards (and sometimes from the 4th) there is a ganglion and ramus for each nerve. The distribution of all these rami down to the 4th lumbar may be considered together. The area of the second thoracic ramus (or of the 1st, as mentioned above) follows on the area of the lowest effective cervical ramus. The 4th lumber ramus supplies either the skin over the 7th lumbar vertebra and a small piece of sacrum or the skin over the sacrum. Between the limits just given for the 2nd thoracic and the fourth lumbar the areas follow on each other, the length of each area being about that of a vertebra.

Below the 4th lumbar nerve is the hind leg region, which is like that of the fore leg already mentioned, in so far as one, two, or three nerves have no dorsal cutaneous branches to the mid-line, and the corresponding rami have no pilo-motor fibres. These nerves are the 5th, 6th, and 7th lumbar.

About the end of the sacrum appears to be the dividing line between the areas of the rami which come from above and those which come from below the ineffective ramus or rami. Thus the skin over the lower part of the sacrum may be supplied by the 4th, 5th, or, perhaps, the 6th lumbar ramus, the skin over the upper coccygeal vertebræ by the 7th lumbar or 1st sacral. The second sacral ramus, as a rule, supplies the hairs of the tail just above the level of the anus and over it; the 3rd sacral ramus supplies the hairs for about an inch and a half below the level of the anus. The coccygeal ganglion gives off rami to the several coccygeal nerves, and these supply different lengths of the tail.

It is easily shown that the area of the skin supplied with pilo-motor fibres by the dorsal cutaneous branch of any given spinal nerve is also supplied by it with sensory fibres. And there is good reason for believing that the fibres of the grey ramus of a nerve, *i.e.* the post-ganglionic sympathetic fibres of a spinal nerve, have in the main the same distribution in the skin as the sensory fibres of the nerve.

Each spinal nerve, from the 1st cervical to the 3rd lumbar, sends fibres to 7 or 8 sympathetic ganglia. For the details of this connection we must refer to the figure appended to the paper.

March 23.—"On the Variation of Surface Energy with Temperature," by William Ramsay, Ph.D., F.R.S., and John Shields, B.Sc., Ph.D.

It is shown that a close analogy exists between the equation for gases,

$$pv = \mathrm{RT},$$

and an equation expressing the relation of surface energy to temperature,

$$\gamma s = \kappa\tau,$$

where γ is surface tension; s, surface; κ, a constant; and τ, temperature measured downwards from a point about 6° below the critical point of the fluid. As the origin of T in the gaseous equation is where $p = 0$, so the origin of τ should be where $\gamma = 0$. Correcting the above equation so that τ shall represent the number of degrees measured downwards from the critical point, the equation becomes

$$\gamma s = \kappa(\tau - d).$$

But even this equation does not express the whole truth. For at temperatures less than 30° below the critical temperature, the relation between surface energy and temperature is not a rectilinear one; a correction is therefore introduced in the form of a second term, which becomes insignificant at temperatures more than 25° or 30° τ; it is

$$\gamma s = \kappa\tau - \kappa d(1 - 10^{-\lambda\tau}).$$

The liquids examined were: ether, methyl formate, ethyl acetate, carbon tetrachloride, benzene, chlorobenzene, acetic acid, and methyl and ethyl alcohols; in fact, the only ones for which data are available. For, in order to calculate γ from the rise in a capillary tube, it is necessary to know the density of the orthobaric liquid and gas; and trustworthy data exist only for these liquids and for a few others which resemble them closely, *e.g.* fluorobenzene, bromobenzene, &c. Also to calculate *s*, *i.e.* *molecular* surface, it is necessary to know the molecular volume of the liquid, and to raise it to the ⅔rds power. Hence $v^{\frac{2}{3}} = s$, or molecular surface; *i.e.* it is possible to compare different liquids on the surfaces of which equal numbers of molecules lie.

Measurements were made at $-89°\cdot8$, the boiling point of nitrous oxide under atmospheric pressure, with ether, methyl formate, ethyl acetate, and the two alcohols; the other substances are solid at that low temperature. These observations confirmed the rectilinear relation with the first three; but in the case of the two alcohols evidence was obtained of molecular association, as also with acetic acid. It is possible to calculate the amount of association at any temperature in such cases. For, as κ is approximately constant for the molecular surface of the "normal" liquids, the equation

$$\kappa/d = x^{\frac{2}{3}},$$

where d is the differential coefficient of an associating liquid, and x is the molecular aggregation, gives the number of simple molecules which have united to form a compound at the temperature chosen. For the alcohols at $-90°$, and for acetic acid a $20°$, the association of molecules approximates to $(C_2H_4O_2)_4$, $(CH_4O)_4$, and $(C_2H_6O)_4$.

We have thus a method by which it is possible to ascertain the molecular complexity of undiluted liquids. The results with the alcohols are shown to agree within resonable limits with those indicated by experiments with strong solutions by Raoult's method.

It is incidentally shown in the course of the paper that there is no angle of contact between liquid and glass, when the liquid surface is in contact only with its own vapour. Ordinary measurements of capillarity give inconstant, and probably inaccurate, results, for it is not the surface tension of the liquid which is measured, but that of a solution of air in the surface film of the liquid.

The paper contains tables and curves exemplifying and illustrating the statements given.

Chemical Society, March 16.—Dr. W. H. Perkin, Vice-President, in the chair.—The following papers were read:—The limits of accuracy of gold bullion assaying and the losses of gold incidental to it, by T. K. Rose. Assays of gold bullion by the ordinary method may be rendered more accurate by the use of a more sensitive balance than is usually employed. The amount of copper or silver contained in the assay piece very considerably influences the "surcharge" or difference in weight between the gold originally present in the assay piece and the cornet finally obtained. The presence of antimony, zinc, tellurium, iron, or nickel reduces the surcharge by quantities which the author has determined. It therefore follows that to ensure accuracy check assays must be made on alloys of the same composition as those under examination. Variations in the surcharge are also caused by changes in temperature of the muffle furnace used in cupellation; a rise of $5°$ in the temperature usually worked at, viz. about $1064°$, is accompanied by a reduction in the surcharge of about $0\cdot01$ per 1000. If attention be paid to the points enumerated above, the gold in bullion of a high degree of purity can be determined within $\pm\ 0\cdot02$ per 1000, the limits of accuracy having been previously considered to be $\pm\ 0\cdot10$ per 1000. The author has estimated the losses of gold in bullion assays. These are due to absorption by the cupel, volatilisation in the muffle and dissolution in the parting acid.—The volatilisation of gold, by T. K. Rose. The author has determined the loss of gold incurred on heating test pieces of the pure metal or its alloys at temperatures between $1045°$ and $1300°$ under various conditions. The loss of gold increases as the temperature rises, pure gold losing four times as much at $1245°$ as at $1090°$. A large amount of gold is volatilised in an atmosphere consisting mainly of carbonic oxide, whilst a small amount only is lost in coal gas. A comparatively small amount of gold is carried away by the more volatile metals, copper appearing to exert an exceptional influence. Metals which are easily volatilised do not appear to be completely driven off at the highest temperatures attained. A larger proportion of gold is lost by alloys which form flat buttons on the cupel than by those which form spherical buttons; it would hence seem that the conditions which lower the surface tension of the gold button also raise the vapour pressure of the metal.—Note on the boiling-point of nitrous oxide at atmospheric pressure, and on the melting-point of solid nitrous oxide, by W. Ramsay and J. Shields. Nitrous oxide boils at $-89°\cdot8$, and melts at $-102°\cdot3$.—The isomerism of the paraffinic aldoximes, by W. R. Dunstan and T. S. Dymond. The importance of the author's discovery of the existence of two acetaldoximes in connection with the theory of the isomerism of oximes is pointed out. The behaviour of the isomerides towards reagents is very similar, the acetyl derivatives prepared from the liquid and solid modifications appearing identical. Both acetaldoximes are converted by hydrogen chloride into the same hydrochloride. The action of phosphoric chloride on the crystalline aldoxime in ethereal solution at a low temperature yields a product which on hydrolysis gives ammonia and acetic acid, as well as methylamine and formic acid; the same products are obtained in almost the same proportion from the liquid aldoxime at a a high temperature. The two isomerides yield only ammonia and acetic acid when treated with phosphorous chloride. Propionaldoxime, Et.CH : NOH, has hitherto been known only as a liquid boiling at $132°$; the authors find, however, that it may be obtained in two forms, the one a liquid and the other a solid melting at $22°$. The solid modification is converted into the liquid one by heating, and the liquid form changes slowly into the solid one on cooling; this behaviour is quite similar to that of the isomeric acetaldoximes. The action of reagents on the acet- and propion-aldoximes is also analogous. It would appear from the above results that further study is needed to establish criteria of stereochemical isomerism in the case of these oximes; the authors are therefore still engaged upon the subject.—The mineral waters of Askern, in Yorkshire, by C. H. Bothamley. The author gives analyses of the waters of four wells or springs at Askern. These waters are accredited with considerable therapeutic value.—Note on the distribution of acidic and alkalinic radicles in a solution containing calcium, magnesium, carbonates, and sulphates; and on the composition of mineral waters, by C. H. Bothamley. The author concludes that if the question of ionic dissociation in solution be put on one side, and mineral waters and solutions of calcium, magnesium, and the carbonic and sulphuric acid radicles, be represented as containing salts as such, the sulphuric radicle must be regarded as combining by preference with magnesium and not with calcium, as is generally supposed.—A magnesium compound of diphenyl, by W. R. Hodgkinson. Magnesium has no action on dry aniline, toluidine, form- and acet-anilid and phthalanil; phenylhydrazine begins to act on magnesium at about $150°$, and at higher temperatures the reaction becomes very violent. Aniline, benzene, ammonia, and nitrogen are evolved and a solid whitish substance containing the metal remains in the retort; on heating this residue an oil is obtained which contains diphenyl. These results suggest the presence of magnesium diphenyl.—Note on acetanhydrocitric acid, by F. Klingemann. The author criticises the recent work of Easterfield and Sell on this acid.—The dissolution of gold in a solution of potassium cyanide, by R. C. Maclaurin. The author shows that the dissolution of gold in potassium cyanide solution is conditioned by the presence of oxygen, and that the amounts of oxygen absorbed and of gold dissolved are in the proportion indicated by Elsner's original equation—

$$4Au + 8KCN + O_2 + 2H_2O = 4AuCN, KCN + 4KHO.$$

Furthermore, it is shown that the rate of dissolution varies with the strength of the solution and that it passes through a maximum in passing from dilute to concentrated solutions; this variation is traced to a decrease in the solubility of oxygen in solutions of potassium cyanide as the concentration increases.

March 27.—Annual General Meeting.—Prof. Crum Brown, F.R.S., President, in the chair.—The President delivered an address in which he discussed the history of the phlogistic theory and its gradual displacement by more modern views. The balance-sheet for the past year was then presented, and the usual votes of thanks passed. A ballot was then taken for the election of officers and Council for the present year.

Mathematical Society, April 13.—Mr. A. B. Kempe, F.R.S., President, in the chair.—The President, calling attention to the title of a paper he had read at the January meeting on the application of Clifford's graphs to ordinary binary quantics (*ante*, p. 382), said that the subject being there regarded from Prof. Clifford's point of view, he had, following the precedent set in a paper by the late Mr. Spottiswoode on Clifford's graphs, associated the name of Clifford only with the graphs in the title. He had, however, on further consideration come to the conclusion that by such exclusive association an impression might be created which would operate unjustly towards the unquestionable originality of the paper by Prof. Sylvester on the application of the new atomic theory to the graphical representation of the invariants and covariants of binary quantics published in the *American Journal of Mathematics*, vol. i. p. 64. By permission of the council he proposed therefore to alter the title of his paper by referring therein to the graphs as "the Sylvester-Clifford graphs."—The following communications were made:—Toroidal functions, by A. B. Basset, F.R.S. The object of this paper is to develop the theory of toroidal functions from a point of view which brings out its connection with the associated functions

$$P_n^m(\nu),\ Q_n^m(\nu),$$

which occur in spherical and spheroidal harmonic analysis. A toroidal function is an associated function of degree $n-\frac{1}{2}$ and order m, where n is zero or any positive integer, and m is zero or any positive integer not greater than n. The paper commences by showing that these functions may be expressed in terms of the definite integrals—

$$P_n^m(\nu)=\frac{(-)^m\Gamma(n+\frac{1}{2})}{\Gamma(n-m+\frac{1}{2}}\int_0^\pi\frac{\cos m\phi d\phi}{\{\nu+(\nu^2-1)^{\frac{1}{2}}\cos\phi\}}n+\tfrac{1}{2},$$

and

$$Q_n^m(\nu)=\frac{(-)^m\Gamma(n+\frac{1}{2})}{\Gamma(n-m+\frac{1}{2})}\int_0^\infty\frac{\cosh m\phi d\phi}{\{\nu+(\nu^2-1)^{\frac{1}{2}}\cosh\phi\}}n+\tfrac{1}{2}.$$

It can easily be proved that these definite integrals satisfy the differential equations for toroidal functions, and the advantages of this method of procedure are twofold. In the first place these integrals lead to certain difference and mixed difference equations connecting functions of different orders and degrees; and in the second place the whole of the analysis and the results will apply when n is changed into $n+\frac{1}{2}$, in which case the integrals become ordinary associated functions. In physical investigations connected with circular vortex rings, functions of degree n and order unity occur, whose properties may be more simply deduced from those of the zonal functions; also $\nu=\cosh\eta$, when η is very large. If, therefore, $\epsilon^{-\eta}=k$, k will be small, and appropriate series can be obtained in terms of k. The latter part of the paper is occupied with the investigation of these series, and it is shown that

$$Q_n=k^{n+\frac{1}{2}}\sum_0^\infty A_s k^{2s},$$

whilst

$$P_n=k^{-n+\frac{1}{2}}(\phi_n\log 4/k+\psi_n),$$

where ϕn, ψn are infinite series of powers of k^2.—Note on the problem to inscribe in one of two given triangles a triangle similar to the other, by Mr. J. Griffiths. The writer discusses the following propositions: (1) A triangle DEF inscribed in a given triangle ABC, so as to be similar to another given one A′B′C′, belongs to some one of twelve systems of similar in-triangles, each system having a centre of similitude of its own. (2) The centres of similitude of the twelve systems in question can be formed into two groups of six points which lie respectively on two circles, inverse to each other with respect to the circumcircle ABC. (3) The centre of similitude of any system of similar triangles inscribed in ABC and having a common Brocard angle equal to that of A′B′C′ will lie on one or other of the above circles. (4) As a particular case of the problem the different systems formed by a triangle DEF inscribed in ABC, so as to be either directly or inversely similar to it are noticed.—The singularity of the optical wave-surface, by J. Larmor, F.R.S. It is shown that two sheets of a wave-surface cannot intersect along a curve. As the elastic quality of a crystalline medium is gradually altered, the separate sheets of its (mechanical) wave-surface may draw together, and may finally come into contact at one or more conical points; but any further alteration in the same direction produces instability. The existence of the abnormality of conical refraction would thus be, on a purely elastic theory, an indication of the immediate approach of instability.—On a problem of conformal representation, by Prof. W. Burnside. The paper deals with those cases in which a rectangular polygon can be represented conformally on a circle or half plane by means of an integral equation between two complex variables. It is formally proved that whenever the polygon can be formed by the juxtaposition of equal and similar figures either

(i) triangle $\frac{\pi}{2}\cdot\frac{\pi}{3}\cdot\frac{\pi}{6}$

(ii) triangle $\frac{\pi}{4}\cdot\frac{\pi}{4}\cdot\frac{\pi}{2}$

(iii) any rectangle

the representation is possible by such an integral equation, and that it is not possible in any other case. A general method for finding the equation carrying out the representation is given, and a few special cases are worked at length. The paper finishes by considering shortly the case in which the polygon is not simply connected, and one or two other allied points.

Linnean Society, April 20.—Prof. Stewart, President, in the chair.—In view of the approaching anniversary meeting the election of auditors took place, when Dr. Meiklejohn and Mr. E. A. Batters were nominated on behalf of the Council, and Messrs. Thomas Christy and W. F. Kirby on behalf of the Fellows.—The President took occasion to notice the retirement of Mr. F. H. Kingston after thirty-six years' service as lodge-keeper, and presented him with a testimonial in the shape of a cigar case containing five and thirty pounds in bank-notes, which had been subscribed on his behalf by all the societies in Burlington House. After a suitable response on the part of the recipient, attention was directed to some photographs of Burlington House with the gateway as it existed before the rebuilding in 1868, and showing the old colonnade which had since been demolished and was lying still uncared for in Battersea Park.—On behalf of Mr. C. Chilton of Dunedin, N.Z., Mr. W. Perry Sladen gave an abstract of a paper on the subterranean crustacea of New Zealand, with remarks on the fauna of caves and wells. The paper contained a *résumé* of previous publications on the subject with additional information from the author's own observation, and an expression of his views on certain controversial points in connection therewith. His remarks were criticised by the President and by Prof. Howes, Dr. Henry Power and Mr. G. Fookes.—A paper was then read by Mr. H. M. Bernard on the anatomy, physiology, and histology of the *Chernetidæ*, with special reference to the rudimentary stigmata, and to a new form of trachea, on which an interesting discussion ensued, and Mr. Bernard replied to the criticisms which were offered.—The society adjourned to May 4.

PARIS.

Academy of Sciences, April 24.—M. Lœwy in the chair.—On the observation of the partial solar eclipse of April 16, made at the Paris Observatory, by M. F. Tisserand. From a measurement of six photographs obtained by MM. Henry, the instants of contact were calculated to have been 3h. 59m. 51s. and 4h. 27m. 59s.—Recent researches on the nitrogen-fixing micro-organisms, by M. Berthelot. From a series of experiments upon samples of earth taken from the Botanic Garden of the École de Pharmacie, it appears that the micro-organisms capable of fixing free nitrogen from the air belong to widely varying species, but that the chief agents are certain bacteria of the soil, seven species of which were isolated. The carbon and hydrogen contained in the atmosphere does not appear capable of supporting the life of these bacteria, and their nourishment is chiefly derived from the decomposition of sugar, tartaric acid, and other hydrocarbons supplied by higher organisms. If there is an abundance of combined nitrogen at hand, the bacteria flourish more profusely, and their absorption of free nitrogen, though placed beyond doubt, has certain definite limits. On the whole, it seems that the carbon-fixing and the nitrogen-fixing organisms fulfil mutually supplementary functions.—On the order of successive appearance of the vessels in the parallel formation of the leaves of certain *Compositæ* (*Tragopagon*, &c.), by M. A. Trécul.—Physiological and therapeutic effects of a liquid extracted from the male sexual gland, by MM. Brown-Séquard and d'Arsonval. Samples of the orchitic liquid for subcutaneous injection were offered to all medical men willing to report upon its effects. Over 1200 physicians availed themselves of this offer, and their results are very encouraging. The malady showing the most striking effect of the remedy was locomotor ataxy, of which 314 out of 342 undoubted cases were cured or considerably improved. Another almost incurable disease which proved very amenable to this treatment was shaking paralysis, of which 25 out of 27 cases were much improved. It appears that the orchitic liquid, though not possessing any direct curative influence upon the various morbid states of the organism, is capable on subcutaneous injection of curing or decidedly ameliorating a great variety of affections, organic or otherwise. This action is due to two kinds of influence. By the one, the nervous system gains in vigour, and becomes capable of improving the dynamical or organic state of the diseased parts; by the other, which depends upon the entrance into the blood of new materials, the liquid contributes to the cure of morbid states by the formation of new cellules and other anatomical elements.—Observation of the solar eclipse of April 16, 1893, at the Lyon Observatory, by M. Ch. André.—Observation of the solar eclipse of April 16 at the Algiers Observatory, by M. Ch. Trépied.—Additional note, by M. Spée.—Spectro-photographic method for the study of the solar corona, by M. George Hale.—On the reduction of any differential system to a linear form and integrable completion of the first order, by M. Riquier.—Verification of the steam counter and its application to the measurement of supersaturation and superheating, by M. H. Parenty.—On the tension of saturated water-vapour, by M. Antoine.—On the measurement of large differences of phase in white light, by M. P. Joubin.—On rational systems of expressions in dimensions of electric and magnetic quantities, by M. E. Mercadier.—Measurement of the difference of phase of two sinusoidal currents, by M. Désiré Korda.—Effect of colouring matters upon actino-electric phenomena, by M. H. Rigollot.—Study of ferric chloride and ferric oxalate solutions; distribution of the ferric oxide between the hydrochloric and the oxalic acid, by M. Georges Lemoine.—On some derivatives of licareol, by M. Ph. Barbier.—On the constitution of gallic blue or tannine indigo, by M. P. Cazeneuve.—On the chloramines, by M. A. Berg.—On bromal bornylates, by M. J. Minguin.—Qualitative and quantitative analyses of formaldehyde, by M. A. Trillat.—On dioptase deposits on the French Congo, by M. Alfred Le Chatelier.—On a zirkoniferous felspathic enclosure in the basaltic rocks of the Puy de Montaudou, near Royat, by M. Ferdinand Gonnard.—On a new mineral species discovered in the copper deposits of Boleo (Lower California, Mexico), by M. E. Cumenge.—On the rocks of the porphyritic series in the French Alps, by M. P. Termier.—On the discovery of the Marine carboniferous in the valley of Saint-Amarin (Haute-Alsace), by M. Mathieu Mieg.—Biological conditions of lacustrine vegetation, by M. Ant. Magnin.—Acclimatisation in France of new Salmonidæ, by M. Daguin.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—Vertebrate Embryology: Dr. A. Milnes Marshall (Smith, Elder, and Co.)—Chemistry for All: W. J. Harrison and R. J. Bailey (Blackie).—Unités et Etalons: C. E. Guillaume (Paris, Gauthier-Villars).—Principes de la Machine a Vapeur: E. Widmann (Paris, Gauthier-Villars). Smithsonian Institution, Report of U.S. National Museum, 1890 (Washington).—The Soil in Relation to Health: H. A. Miers and R. Crosskey (Macmillan).—Wm. Kitchen Parker, F.R.S.: T. Jeffery Parker (Macmillan).—Types of Animal Life: St. G. Mivart (Osgood).—Advanced Physiography: R. A. Gregory and J. Christie (Hughes).—Gun and Camera in Southern Africa: H. A Bryden (Stanford).—Alembic Club Reprints; No. 1, Experiments upon Magnesia Alba, Quicklime, &c.: Dr. J. Black (Edinburgh, Clay).

Pamphlets.—Vererbungsgesetze und ihre Anwendung auf den Menschen: S. S. Buckman (Leipzig, Günthers).—City and Guilds of London Institute; Report to the Governors, April (London).—The Stæchiological Cure of Consumption, &c.: Dr. J. F. Churchill (Stott).

Serials.—Quarterly Journal of Microscopical Science, April (Churchill).—Bulletin of the New York Mathematical Society, vol. 2, No. 7 (New York).—Ergebnisse der Meteorologischen Beobachtungen, Jahrgang 2 (Bremen).—Seismological Society of Japan, vol. 1, 1893 (Yokohama).—Geological Magazine, May (K. Paul).—Natural Science, May (Macmillan).

DIARY OF SOCIETIES.

London.

THURSDAY, May 4.

Royal Society, at 4.30.—On the Thickness and Electrical Resistance of Thin Liquid Films: Prof. Reinold, F.R.S., and Prof. Rücker, F.R.S.—Organic Oximides; a Research on their Pharmacology: Dr. H. Pomfret.—On the Alleged Increase of Cancer: Geo. King and Dr. Newsholme.—Further Experimental Note on the Correlation of Action of Antagonistic Muscles: Dr. Sherrington. On the Differential Co-variants of Plane Curves, and the Operators Employed in their Development: R. F. Gwyther.

Linnean Society, at 8.—Nervous System of Myxine glutinosa: Alfred Sanders.—On Polynesian Plants collected by J. J. Lister; W. B. Hemsley, F.R.S.

Chemical Society, at 8.—Ballot for the Election of Fellows.—Hydrates of Potassium, Sodium, and Lithium Hydroxides: S. U. Pickering, F.R.S.—Notes on Marsh's and Renich's Tests for Arsenic: Dr. J. Clark.—The Formation of Hydrogen Peroxide in Organic Liquids: Dr. A. Richardson.—The Supposed Saponification of Linseed Oil by White Lead: J. B. Hannay and A. E. Leighton.—Notes on the Capillary Separation of Substances in Solution: L. Reed.

Institution of Civil Engineers, at 8.—The First James Forrest Lecture—The Interdependence of Abstract Science and Engineering: Dr William Anderson, F.R.S.

Royal Institution, at 3.—The Atmosphere: Prof. Dewar, F.R.S.

FRIDAY, May 5.

Chemical Society, at 8.—Hofmann Memorial Meeting.—Address by Right Hon. Lord Playfair, F.R.S.; Sir F. A. Abel, F.R.S.; W. H. Perkin, F.R.S.

Royal Institution, at 9.—Fogs, Clouds, and Lightning: Shelford Bidwell, F.R.S.

SATURDAY, May 6.

Royal Institution, at 3.—Johnson and Milton: Dr. Henry Craik, C.B.

MONDAY, May 8.

A BOOK ON PHYSIOGRAPHY.

"*A. E. Brehm. Les Merveilles de la Nature.*" *La Terre, les Mers, et les Continents; Géographie Physique, Géologie et Minéralogie.* Par Fernand Priem. (Paris: J. B. Baillière et Fils, 1892.)

THE wonders of nature! The book would be worth having that would help us to realise, however imperfectly, what it is that underlies this hackneyed phrase. But the book that shall create and satisfy a craving for this result will not be easy to build up. It must be encyclopædic, but (need it be said?) not an encyclopædia. It must be accurate to the last degree of accuracy, but must have nothing of the pedant about it. Human interests must, wherever an opportunity offers, be interwoven with its narrative. The narrative itself must be, not the heavy didactic prosing of an old-fashioned schoolmaster, but the congenial living talk of a friend. Sound judgment must pick out what is to be told and what left unsaid. So far from looking upon all facts as of equal value, the utmost care must be exercised to present those only which are within the grasp of the lay mind; all that has significance for the specialist only will be out of place. Nothing will be inserted merely because it is curious or marvellous, for the object will be not to make the reader gape like an astonished clown at something which looks very extraordinary because he does not understand it; rather to use the emotion of wonder as a means to something beyond, as an inducement to look below the surface and find out how results so startling have been brought about. The right book must be neither shallow nor deep; fascinating as a poem, but sound as a scientific treatise; and it will be well if there run through all of it some one leading idea, which will serve to give it unity and string together into a connected whole the sections of which it is made up.

Under the title of "Les Merveilles de la Nature" a series of works is being published which seem to be intended for what is usually known as the "general reader." The preceding volumes have dealt with animal life, the volume now before us is devoted to Erdkunde. It will be possible, without pretending to deal with the whole of the bulky volume, to inquire how far it appears likely to meet the requirements of those readers for whom it seems intended. The work opens with "Données générales de la Géologie," and the commencement is promising; the treatment is broad, and illustrations are supplied of the general truths enunciated. But already, on p. 5, we see how little judgment has been exercised in the selection of materials. Of what interest or of what educational value to the general reader can be such technical details as a description of the way of measuring dip and strike in the field, and a figure of a pocket compass? A few pages further on we have a compressed summary of the succession and life of the main geological epochs, and some well-executed figures of their fossils. The account is far too meagre to be of any real use, and it is difficult to see what principle has guided the selection of the fossils. There is a "casualness" too about some statements calculated to mislead; as when we find no mention of Brachiopods in the Silurian and Carboniferous, but the emphatic assertion that the Devonian fauna is specially characterised by the presence of numerous Brachiopods. Again it is true enough that the Triassic fauna "diffère notablement de la fauna paléozoïque;" but the fact that it contains a mixture of palæozoic and mesozoic forms is at least of equal importance. These instances, picked at random, show how much of a compilation and how little of a masterly abstract is offered to the reader. A history of the progress of geology is one of those things specially suited to such a work as the present. We have one here interestingly written, though perhaps the salient points do not stand out as boldly as could be wished.

Further on, under the heads of mineralogy and petrology, we have a vast array of facts of very unequal interest or value for ordinary readers. What good can it be to any one to be told that there are six or seven systems of crystallisation, when he is never told what is meant by a "system"? Symmetry, which lies at the base of crystallographic classification, is barely mentioned, and most imperfectly explained. But what an attractive and instructive story may be made about crystals! Some of the more elementary facts about their symmetry and probable molecular structure are not hard to grasp, and furnish fascinating illustrations of law and harmony. Looked at in this light, these flowers of the inorganic world cease to be mere glittering gauds, and tell a tale that all would follow with delight. Out of Ruskin, checked by Miller, such might be constructed in place of this dull assemblage of barren and imperfectly explained facts. When we come to the microscopic examination of rocks there is much that is too detailed for the general public and not full enough for the specialist.

The nationality of the book must be the excuse for the survival of such statements as the following:—"Le granite est la roche éruptive la plus ancienne. . . . Ses éruptions se sont faites pour la plupart avant le dépôt des roches sédementaires: le plus récentes paraissent dater du cambrien." "Les porphyres pétrosiliceuse sont charactéristiques de l'époque permienne." But surely any one whose knowledge went beyond a few books would have thought it fair to say that these views were not universally adopted, though they are held by some of the most distinguished of his countrymen.

Turning to other branches of knowledge, the critic is still compelled to take serious objection to much that he meets with. Solar and stellar physics are scarcely up to date, though perhaps there is enough for a book of this class. It will be hard for any one who depends upon this book alone to gather how the shape of the earth is ascertained. It is all very well to copy out of a book that an arc of 1° is so long in Peru and so long in Lapland, but there is no word said as to how astronomers find out that they have travelled over 1° of latitude, nor of the trigonometrical survey requisite to measure the length of the arc. These points are easy enough of explanation, and if in place of the misleading cut on Fig. 64 a figure had been given with the necessary explanation, we should have had something of educational value instead of a mere transcript. Statements are made with great confidence about the time of rotation of Mercury and the inclination of the axis of Venus and of the prodigious height of the mountains on these two planets; they certainly ought not to have been put down as well-ascertained matters of fact. Figs. 67 and 68 I confess are beyond me.

These samples, culled from different parts of the book, are enough to give a fair idea of its general character, and the impression made on my mind by a general perusal is that it is by no means an ideal performance. But there is much that is attractive about it. It is crowded with illustrations, many of them artistic and apposite, though in the case of some it is hard to see upon what they are intended to throw light. With children it will be deservedly a favourite. I think I know a boy, of some eight or nine years, not much addicted to reading, who will devour the "pictures" and render the life of his elders a burden by the countless questions they suggest. And the elders will, many of them, find in it much interesting matter; and if what they read is not always quite sound and here and there a little dismal, there is much that is lively and stirring and to which no exception can be taken on the score of accuracy. We may wish the book good speed till something better of its kind displaces it.

A. H. Green.

SIR W. BOWMAN'S COLLECTED PAPERS.

The Collected Papers of Sir William Bowman, Bart., F.R.S. Edited for the Committee of the "Bowman Testimonial Fund," by J. Burdon Sanderson, M.D., F.R.S., and J. W. Hulke, F.R.S. In two volumes. (London: Harrison and Sons, 1892.)

No more fitting record of a well-spent life could have been given to the world than these two volumes, containing "The Collected Papers" of the late Sir William Bowman.

In July, 1888, the "Bowman Testimonial Fund" was inaugurated. Its design was to make to Sir William Bowman some acknowledgment of the appreciation in which he was held on account of his high personal character and of his professional and scientific attainments. This took first the form of a portrait of himself by Mr. Ouless, R.A., and further of a republication at least in great measure of his various scientific memoirs. These memoirs have been edited, with the assistance of the author, by Prof. Burdon Sanderson and Mr. Hulke.

The first volume contains the whole "of the epoch-making researches which were accomplished by Sir William Bowman between forty and fifty years ago in the field which he himself designated as that of 'Physiological Anatomy,'" for he regarded the discovery and uses parts as the main purpose of anatomical investigation. This volume has been edited by Prof. J. Burdon Sanderson, and contains three memoirs from the "Philosophical Transactions" on the minute structure and movements of voluntary muscle; on the contraction of voluntary muscle in the living body; and on the structure and use of the Malphigian bodies of the kidney, with observations on the circulation through that gland; also the author's contributions to "The Physiological Anatomy and Physiology of Man." This work was published between 1839 and 1856, by Drs. Todd and Bowman, and we learn the interesting details that out of a total of 298 illustrations to the two volumes, 120 of these were from the drawings of Bowman. This volume concludes with four contributions to the "Cyclopædia of Anatomy and Physiology" on Mucous Membrane; on Muscle; on Muscular Motion; and on the Pacinian Bodies.

The second volume comprises a selection of "reprints," together with some papers, now first printed, under the headings miscellaneous, surgical, and ophthalmological. These have been selected from a large amount of material, and arranged with the assistance of the author. This volume has been edited by Mr. J. W. Hulke, who writes that, "read from the standpoint of the time when each was written, these memoirs, in addition to their intrinsic merits, have, as marking the views and opinions then prevalent, a distinct value for the student interested in the history of modern medicine."

The work is prefaced by a brief memoir by Henry Power, in which he reminds us that this man of many parts and much learning "had a clear idea of the relative value of the different branches of knowledge associated with medicine, and that he recognised the futility of any endeavour on the part of the student to make himself a profound chemist, botanist, or physiologist, believing that such an attempt necessarily leads to the neglect of the practical subjects which are the occasion for which these foundation sciences are studied. No one knew better than he that 'ex libris nemo evasit artifex,' the scene of the labours of the student, was, in his opinion, at the bed-side of the patient." These ideas of Bowman are of especial importance in these days, when the tendency of the teaching in our medical schools is for each teacher to try to make his subject the one alone necessary, instead of its being but a small part of an important whole. The sketch, which is all too short, is appreciative and sympathetic. One little trait we miss; while the great physiologist's love of country life is hinted at, his love for and knowledge of flowers is passed over, and yet those who were privileged to know him in his days of well-earned rest and leisure will remember what a delight his garden was to him. Two portraits are given; both are photographs. One is of the painting by G. F. Watts, R.A., of Bowman when forty-eight years of age. This hardly does justice to the original painting, and one is of the painting by W. W. Ouless, R.A., which was done for the "Testimonial Committee Fund," in 1889, when Bowman was in his seventy-third year. This is an excellent and pleasing likeness.

OUR BOOK SHELF.

Aids to Biology. By Joseph W. Williams. (London: Baillière, Tindall and Cox.) (Students' Aids Series.)

This little volume of 142 pages, small octavo, is the second work which has reached us written up to the standard of the first examination of the Conjoint Board of the Royal Colleges of Physicians and Surgeons. The information which it contains is transcribed from the best sources available, and the author has woven the excerpts into a very presentable whole, written in good, clear style, and exceptionally free of gross errors. The pages of the volume are enlivened by thirty-nine small woodcuts and a well-chosen epilogue from Broca, and there are added a useful "index glossary," and a series of "test questions," largely culled from examination papers of the past. The work is by no means destitute of small incongruities and an occasional misuse of technical terms; and the most serious errors which it contains, contrary to the general rule, involve leading rather than subsidiary topics. The description of "living matter" as existing in the "colloidal condition" and (two pages further on) as "a semi-fluid granular substance . . . unable to absorb colouring matters when living"; the alleged origin of the cœlome of "all animals above the cœlenterata" by "the splitting of the mesoblast"; the assumption that the contractile vacuole of the protozoa is a respiratory organ "pumping in oxygenated water," and "furnishing oxygen to the animal by means of its rhythmical dilatations"; the confusion under the term "paraplasm" between modified portions of the cell-protoplasm and products of its living metabolism, with the correlated description of the protoplasm of the egg cell as a "vitellus, or yolk"; and the description of sclerenchyma as "stony tissue," are cases in point. We note with satisfaction the prominence given to the physiological and more purely chemical aspects of the subject, too often neglected in minor works on general biology. Conspicuous among leading dogmas formulated is the assertion that with the exception of ascidians and some infusorians the animal "does not contain cellulose," with the implication that certain animals form chlorophyll. We venture to think that the time has now arrived when the investigations of Beyerinck, Famintzin, Von Graff, and Haberlandt, Ambronn, and others, which have lately revolutionised our knowledge on these vitally important topics, should find expression in the elementary class-book. The author remarks in his preface that "it must be remembered that biology can be learnt in no other way than with the scalpel and the microscope," and that his volume is intended "simply and solely for the purpose of revising" a practical knowledge which the student has gained under the guidance of his teachers, "especially during the few weeks previous to the time when he intends to cross the threshold of the examination hall." If this line of conduct can be ensured, the work will fulfil a good purpose; but it may be doubted whether the overtaught medical student of to-day will regard the book as anything but a cram one. It has been compiled at considerable pains and with marked success; but as the dispensation which it seeks to further cannot possibly endure, we wish we could congratulate the author upon a devotion to some more permanent and desirable object.

Public Health Problems. By John F. J. Sykes. Illustrated. (London: Walter Scott)

THE author of this volume—which forms one of the Contemporary Science Series—has sought "to bring to a focus some of the essential points in evolution, environment, parasitism, prophylaxis, and sanitation, bearing upon the preservation of public health." It was impossible for him to deal fully in the space at his disposal with any particular part of so vast a subject, but he has contrived to give a very clear and interesting idea of the main lines of inquiry with which workers in the public health service are chiefly concerned. First he treats of internal and external influences affecting health, these influences being heredity, physical influences (light and heat), chemical media, and biological agents. Then he discusses the following aspects of communicable diseases—causation, parasitism, dissemination, and modifications. Afterwards there are series of chapters on defensive measures against communicable diseases, and on the urban dwelling. Mr. Sykes, as medical officer of health for St. Pancras and honorary secretary of the Incorporated Society of Medical Officers of Health, has had ample opportunity for the study of the questions on which he discourses, and his book ought to be of good service in disseminating sound ideas as to the conditions on compliance with which the attainment of a higher standard of public health depends.

Galenic Pharmacy. By R. A. Cripps. (London: J. and A. Churchill, 1893.)

THE student of pharmacy will, no doubt, find plenty of instructive information in this book. It does not, however, call for an extended notice in this journal, as the author does not attempt a scientific treatment of the subject, but confines himself to dealing with it on the old lines. The various pharmaceutical operations of solution, infusion, &c., are fully described, but no attempt is made to arrange the facts on any than an empirical basis. The time has arrived, however, when pharmacy should be expounded in a more scientific manner, and many barbaric and obsolete processes excluded or re-modelled in the light of our present chemical and pharmacological knowledge.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Mr. H. O. Forbes's Discoveries in the Chatham Islands.

IN a paper read before the Royal Geographical Society on March 12th, and again in an article on "The Chatham Islands and their Story" in the *Fortnightly Review* of this month, Mr. H. O. Forbes has described his very interesting discoveries in these islands, and has founded thereon certain conclusions as to the past history of the New Zealand group. The most startling new fact is the proof of the recent existence on the Chatham Islands of two birds whose nearest allies inhabited the distant group of the Mascarene Islands within the historical period. These are a flightless rail very closely allied to the Aphanapteryx of Mauritius, and a coot which is hardly different, except in its somewhat larger size, from the extinct *Fulica newtoni* of the same island.

It is on the flightless rail that Mr. Forbes mainly dwells in his deductions of past changes which it is supposed to imply, and it is on these deductions only that I wish to make a few remarks. He quotes Prof. A. Newton and his brother as stating that the solitaire of Roderiquez and the Dodo of Mauritius, being evidently of one stock, and there being analogous facts in the adjacent islands, they are compelled to believe that "there was once a time when Roderiquez, Mauritius, Bourbon, Madagascar, and the Seychelles were connected by dry land"; and he then argues that there must also have been a continuous land surface between this land and the ancient land comprising New Zealand and the surrounding islands. This connecting land he supposes to have been the Antarctic continent during a mild period and with great extensions over the southern ocean. When the Antarctic ice age came on the inhabitants of this continent had to migrate northwards, and some, "such as the genus Aphanapteryx, would seem to have split into parties, which, travelling by divergent roads, finally arrived in regions so far apart as Mauritius and the Chatham Islands, unaffected by the varying climates and surroundings they experienced, being of an ancient dominating type."

It is this tremendous hypothesis which appears to me to be not only quite unnecessary to explain the facts, but also to be inadequate to explain them. If one thing more than another is clear, it is that these comparatively small flightless birds were developed, as such, in or near to the islands where they are now found, since they could not possibly have arisen on any extensive land inhabited by carnivorous mammals and reptiles, and, if introduced into such a country, could not long survive. So far as I am aware, no doubt has ever been expressed on this point, the evidence for it being so clear and its explanation on the theory of evolution so complete; and I hardly think that Prof. Newton would now maintain that the affinities of the flightless birds of Mauritius, Bourbon, and Roderiquez implied the former union of these truly oceanic islands. Allied forms of ancestral flying birds may have reached the islands without such union;

and, owing to the total absence of terrestrial enemies and the abundance of food, may have developed into the allied flightless birds whose remains are found there.

But Mr. Forbes speaks of the genus Aphanapteryx itself, presumably therefore flightless, inhabiting the Antarctic continent, and migrating northwards by two routes of about 2000 miles each, in which case, this enormous extent of land must have been as free from all carnivorous land mammals and reptiles as New Zealand and Mauritius are now. If however, the birds in question lost their powers of flight in or near the islands where their remains are found, all difficulties of this kind disappear. The Aphanapteryx belongs to a family, the Rallidæ or rails, of world-wide distribution, while many of the component genera are also almost cosmopolitan, and are represented by closely allied species in distant regions. What difficulty, therefore, is there in the same or closely allied species of this widespread group finding their way at some remote epoch to Mauritius and the Chatham Islands, and, from similar causes in both islands, losing their power of flight while retaining their general similarity of structure? To put the matter briefly: if the common ancestors of the Aphanapteryx of Mauritius and the Chatham Islands were flightless, they could not have reached those islands from the Antarctic continent owing to the length of route and the presence of enemies; while if they possessed the power of flight no important change in land-distribution is required.

I have discussed this one point only, because it illustrates the very common practice of explaining each fresh anomaly of distribution by enormous changes of physical geography, when a much more satisfactory explanation can be given involving no such vast and unsupported revolutions in the earth's surface. I am aware that Mr. Forbes adduces many other facts and considerations in support of his view as to the former extension and habitability of the Antartic continent, some of which appear to me to be valid and others the reverse. On most of these I have already expressed an opinion in my "Island Life"; and I only write now in order to point out that the very remarkable and interesting facts, whose discovery we owe to Mr. Forbes's energy and perseverance, do not add anything to the evidence already adduced for that view, but may be best explained in a far simpler manner, and without requiring any important changes in the geography of the southern hemisphere.

Alfred R. Wallace.

Swarms of Amphipods.

Once last winter on entering the laboratory here after it had been shut up for a few days, we found the floor, tables, shelves, window-ledges, and even dishes on the highest shelves, covered with great numbers of dead amphipods. These were found to be *Orchestia gammarellus* (the shore-hopper). About ten days ago an unusually high tide occurred, and the curator and others who were working in the biological station noticed that the steps leading to the beach were swarming with amphipods. On investigating further it was found that the amphipods were coming up in great numbers from high-water mark, that they jumped up the steps, and that they climbed the vertical concrete wall surrounding the station to a height of several feet. Many of them were found about twelve feet above the sea, having come nearly all the way on artificial ground (concrete steps and wall), and they were so abundant on the platform outside the laboratory door that it was impossible to put a foot down without treading on many. Specimens were kept, and Mr. A. O. Walker, who is here with me now, finds that these also are *Orchestia gammarellus.* This species lives normally at or about high-water mark, and it is abundant here under stones at that line, but Mr. Walker tells me that he has taken it on the one hand nearly at low-water mark, and on the other hand under stones on grass, along with beetles, and we have found it near here far above high-water mark at the side of the road. However, these last are probably exceptional cases, and we are both inclined to think that the two amphipod invasions noticed here have been caused by the Orchestias being driven from their usual haunts by exceptionally high tides. But whether a panic arises on the flooding of their homes, or they lose their way on our concrete, the fact remains that whereas the sea was only a couple of feet higher than an ordinary high tide the amphipods ascended on the one occasion to about twelve and on the other to perhaps twenty feet above their usual level.

Port Erin, April 29. W. A. Herdman.

A Difficulty in Weismannism Resolved.

Weismann's essay "On the Significance of Sexual Repr duction in the Theory of Natural Selection," published in 188 enunciates the thesis that the object of sexual reproduction is " create those individual differences which form the material out which natural selection produces new species." This thesis w developed in the essay, "On the Number of Polar Bodies a Their Significance in Heredity" (1887), and still further "Amphimixis," published late in 1891.

While "Amphimixis" must have been nearly ready, I wro to Nature (vol. xliv. p. 613), under the heading, " Difficulty in Weismannism," pointing out *a posteriori* the co plete insufficiency of sexual reproduction, by merely shuffli ancestral germ-plasms, to effect indefinite specific variation the lines adopted by Weismann. My friend, Mr. Poulton, wro (vol. xlv. p. 52) accepting my summary of Weismann's vie "as fair statements," but criticising the deductions is not allo ing for the effect of different groupings of the ancestral plasms the germ-cells, and regretting that I had not awaited the pu lication of "Amphimixis," as "Prof. Weismann tells me," wrote, "that the points raised by Prof. Hartog are consider in this treatise." Mr. Trow also wrote (vol. xlv. p. 102), urgi that I had not allowed for the simultaneous action of natu selection or for the combinations of germ-plasms. In reply my rejoinder of the same date, Mr. Trow again urged that I h not taken natural selection into account, and that I had m understood Weismann's position. The controversy was th closed.

However, neither the German edition of "Amphimixis," n the authorised English translation published about six mont later, contained the solution of my difficulty that was anticipat by Mr. Poulton. There runs through the book like a red thre the conception of 1886, that sexual reproduction is the creat of the variations on which natural selection acts. A referen of mine to the inadequacy of this, Weismann's Theory Variation, contained in an article in the *Contemporary Revi* for July, 1892 ("Problems of Reproduction"), passed witho answer or comment, so far as I know.

In "The Germ Plasm, a Theory of Heredity" (189 Weismann devotes chapter xiv. to the consideration of heredi Herein I find the following theses, in which I preserve t italics of the original (English edition):—

1. "*It* [sc. amphimixis] *is not the primary cause of he ditary variation,*" p. 414.

2. "*The cause of hereditary variation must lie deeper th this* [amphimixis]. *It must be due to the direct effect of extern influences on the biophors and determinants*" [sc. of the ge plasms or ids], p. 415.

3. "*The origin of a variation* is equally independent selection and amphimixis, and is due to the constant occurre of slight inequalities of nutrition in the germ plasm," p. 431.

Obviously the position of 1886–91 has been abandoned untenable. If we ask why, the answer is probably contain in the following passage and annexed note ("Germ Plasm pp. 434–5):—

"It has recently been maintained that as a consequence my theory I must adopt one of two alternatives, and assu either that the germ plasm of the higher animals consists of of the primitive protozoan ancestors, or that every id is co structed in accordance with the existing character of t species; my real view, however, is intermediate between th two." The note runs: "Compare Marcus Hartog, Natu vol. xliv. p. 102." The reference omits my letter of Octo 31, 1891. The deductions made by this author from my form views are logically correct, but are no longer justifiable, sinc myself have gained further insight into the problems co cerned.

It follows from the above—

1. That Weismann has withdrawn his whole theory of spec variation as created by sexual reproduction.

2. That my account of his views on the point at issue in 18 was both full and fair.

3. That in 1891 no one else, not even Prof. Weismann, h perceived that "logically correct" deductions from his gene theory of the germ plasm were fatal to his theory of variatio

4. That the Weismannism of to-day regards the action external forces as the one essential cause of variation, so approximates to the teachings of the older evolutionists.

As no reference is made in the preface to this matter, even in the index (for which Prof. Weismann is not responsib

. wish to draw attention to it—all the more since so competent . writer as "D. H. S." seems in a review in NATURE (April :7) to be unaware that the theory of variation by amphimixis [1] ias ceased to exist as a "Difficulty in Weismannism."

Cork, May 1. MARCUS HARTOG.

Medical Biology.

G. B. H. HAS, I am glad to see, criticised effectively the yllabus of Elementary Biology put forth by the Conjoint Board NATURE, vol. xlvii. p. 530). A less fortunate course of study could iardly have been devised. The students who take the course nclude a number whose previous education, energy and ambition .re not sufficient to encourage them to attempt a university ;ourse, and the average quality is therefore not very good. They vork through a number of unicellular types, which give no raining for the hands, though they are no doubt useful in other ways. Then come Hydra and the Leech. Hydra is of course a good subject. The Leech is not instructive to a student who ias no knowledge of similar animals, and the untrained man cannot possibly dissect it for himself. The rest of the course consists of parasitic worms and certain generalities. The parasitic worms commonly have the nervous system, heart, and sometimes even the alimentary canal absent or poorly developed, while the reproductive organs are of extraordinary complexity. From these the student has mainly to derive his notions of the plans of structure which are found among animals. Such a course of study looks practical, but it is almost pure waste of ime. It does not teach the student to dissect, nor does it ntroduce him to those problems of Nature which are most accessible to a beginner. In fact, the whole course may be expected to evaporate shortly, leaving behind nothing more valuable than a recollection of the outward appearance of certain parasitic worms.

When the teacher attempts to introduce more instructive subjects, the class, solely bent upon satisfying the Conjoint Board, are too apt to scamp the work, with this excuse, that their prescribed course cannot have aroused any interest in Biology. Educationally, the syllabus of the Conjoint Board is a sin.

L. C. M.

Afterglows in Spain.

I HAVE read Mr. Backhouse's note in NATURE (vol. xlvii. p. 582) on the afterglows as seen by him in Spain during February last, and the doubts he expresses on the question whether this phenomenon has always occurred when the sun has been near the horizon. I have observed for many years the setting of the sun in Cadiz on the sea horizon with the purest sky, and never remarked the pink tint, but always the rosy tint in the west and the purple, or *Cegensghein*, in the east. After the Krakatão eruption, in the clear sky of Madrid, the pink colour of the segment was always more or less visible; and it has been more marked in these later afterglows. The phenomenon is of the same character as that of 1883, but much less brilliant. The apex of the segment rises frequently to 40°.

I have also many times observed the *green ray* (rayon vert) in very different conditions of the atmosphere, but nearly always with calm air; this is not precisely a ray, but a flash of green light that has a very perceptible duration of some tenths of a second. AUGUSTO ARCIMIS.

Madrid, April 24.

Soot-figures on Ceilings.

THE phenomenon noted by Mr. Poulton in NATURE (vol. xlvii. p. 608) is a matter of very common observation; except in the detail of the nail-heads it has been often noticed. The explanation is, I fancy, simpler than that suggested by Prof. Lodge. It is probably a simple case of *sifting of air*, as it passes by upward diffusion through the porous plaster, where its passage is not barred by contact of the plaster with the wood on the upper side. The plaster acts as the plaster of Paris plug does in the classical researches of Graham on the diffusion of gases, and as the plug of cotton-wool does in the common process of sterilising air in biological work. That warm air does stream up through a plaster-ceiling in this way is a matter of experience to every householder, when in the winter a bedroom over a sitting-room in which a fire is kept burning all day and a lamp or gas-flames for some hours in the evening, is always found to be drier and warmer than another room in the same house not so situated. We can scarcely classify dry wood and iron together as conductors of heat. A. IRVING.

Wellington College, Berks, April 29.

THE soot-figures on ceilings described by Mr. Poulton remind me of the appearance of very similar figures brought out by hoar-frost. The first time I noticed this effect was on the surface of a smoothly-boarded gate, where the parts behind which the bars of the framing ran were marked out by a much thicker coating of hoar-frost than the rest. Subsequently I noticed the same effect on a wooden pier where the planking was crossed by broad belts of white, exactly outlining the timbers to which the boards were nailed. On another occasion thick hoar-frost had formed on the roof of the after-cabin of the steam yacht *Medusa*, composed of a close pile of fine needles of ice about one-eighth of an inch high, inclined at various angles. At first the places where the thin teak boards were nailed to the cross-beams were covered only a little more thickly than the rest, but as the warmth of the day increased the ice spicules disappeared—evaporated rather than melted—from the unsupported parts, but remained in a broad band outlining each beam except above the nail-heads, over each of which a small clear space had melted.

At the time I satisfied myself that the phenomena were due to peculiarities of melting rather than of deposition. Supposing the whole surface to have been coated uniformly, the thicker parts would take longer to heat up by the sun, and so tend to prolong the life of the ice spicules resting on them. If this were so, conversely the thickened parts of the structure, cooling more slowly, should have received a lighter coating to begin with, but this I was never fortunate enough to observe. Is the similarity to the soot-figures accidental? HUGH ROBERT MILL.

1, Savile-row, April 28.

AS this subject has been under discussion lately in NATURE, it seems worth while recording a striking instance which must be well known to many who have been in the large mess room of the Royal Engineers at Chatham. This room has a lofty, highly ornamented ceiling, which was for many years bordered with a deep cornice with a plain moulding either in plaster or papier maché, mostly stuck on one simple template, and coloured either white or some very pale tint. The room was lit by three sunlights in the roof, containing about 190 gas jets. In the course of time the whole of the white moulded cornice became grey with soot-deposit *marked at intervals with light bars*, which were apparently the outline of the wooden ribs carrying the mouldings. This pattern was fairly conspicuous, and was often a subject of discussion at mess (1885 to 1890). Dr. A. Lodge's explanation of the cause seems to be the true explanation. ALLAN CUNNINGHAM.

Kensington, April 28.

THE mapping out of the heads of nails driven into the joists of the ceiling at Felixstowe seems to be inexplicable by the theory of filtration, although this may very probably account for the more common cases of a deposit between but not upon the joists of a ceiling. I am endeavouring to get a photograph of the best part of the Felixstowe ceiling. Dr. Mill's observation seems to be due, as he suggests, to a different process.

E. B. POULTON.

THE APPRECIATION OF SCIENCE BY GERMAN MANUFACTURERS.

RECENTLY, when giving evidence before the Gresham University Commission, I had occasion to speak of the attention devoted in German chemical laboratories to higher studies, and when asked what were the results of this instruction I drew attention to an article published a short time before in that most enterprising of chemical periodicals, the *Chemiker-Zeitung*, edited by Dr. Krause. In this article a description is given of the research laboratory provided to accommodate *six and twenty skilled chemists*, attached to the works of the Farbenfabriken,

[1] As regards the origin of new species, the author, like Prof. Weismann, attributes the greatest importance to sexual reproduction, and especially to cross fertilisation" (see ante, p. 606).

vormals F. Bayer and Co., of Elberfeld, who are manufacturers of dye-stuffs and other products derivable from tars. I told the Commissioners that if, at the present time, it were desired to fit up a research laboratory for chemical purposes in London, we could not do better than take these plans and reproduce them in their entirety, and that we should then, I believed, have reason to congratulate ourselves on possessing the best-appointed public research laboratory in the world.

In addition to the two dozen skilled chemists in the research department at the Elberfeld works, a large number are engaged in other departments, the total number employed being, I believe, over *sixty !*

The Elberfeld works do not stand alone: the world-renowned Badische Anilin and Sodafabrik probably has in the aggregate far more laboratory accommodation than is provided even at Elberfeld. I learn from my friend Dr. Caro, that of the *seventy-eight* chemists in the employ of this firm fifty-six have the Ph.D. degree.

At many other works equally ample provision is made—in fact the colour works throughout Germany are simply laboratories on a very large scale.

As an antithesis, I may add that I told the Gresham Commissioners that I did not think that any English colour works had six skilled chemists in its employ; at all events six was the maximum number.

Is it then surprising that, notwithstanding that a very large proportion of the coal-tar used is of English origin, and that both the "aniline-colour" and the alizarin industry were first established here, according to a statement in the Chicago Exhibition Catalogue of the German Section, about nine-tenths of the total quantity of artificial colouring matters now produced is manufactured in Germany? Whatever the proportion, in 1891, Germany exported aniline-colours of the estimated value of no less than 44,269,000 marks, and alizarin valued at 12,906,000 marks—or little short of three millions sterling—a very large proportion of these manufactured colouring matters being sent to the East Indies, where they are fast displacing those of natural origin. Dr. Caro in a comprehensive monograph just published in the *Berichte* in which the gradual development of the coal-tar colour industry is fully traced out, speaks of it as a German *national industry. Manufactured in Germany* is certainly now the recognized trade mark for chemicals throughout the world.

Not many years ago Wurtz wrote, with reference to the origin of the science, "La chimie est une science française;" at the present day we may say, without fear of contradiction, that, whatever its origin, it is now a German science; that it is to this fact that the Germans owe their supremacy; and that it is to our failure to feel the pulse of the times, and to educate ourselves up to the proper point that we owe our downfall. It is to be feared, moreover, that unless we realise this without further loss of time, and hasten to fit ourselves to do our fair share of the work, other industries in which chemistry plays an important part, ere another twenty years are past, will also have quitted our shores. To do this we must put aside the idea that University extension and County Council lectures, or even polytechnics and technical schools for the multitude, are to bring about the necessary reform; and we must rise above the belief that a degree given for text-book knowledge and an acquaintance with the ordinary methods of analysis is evidence of competency. A true conception of what a chemist is—what he is called on to do and to know in this age of progress—must arise in high quarters and especially among our manufacturers.

FIG. 1.—Laboratory as seen from the street; Works on right, Offices on left.

Our children must be properly taught at school and trained to work as well as to play, and we must cease to worry their lives at college by insisting on the study of a multiplicity of subjects, and no longer attempt to develope a Chinese system of examinations. Surely it is time that we realised that our examination system is a fraudulent failure. In Germany the victory has been gained wholly and solely through the agency of the Universities—here we are still dominated by influences which had their origin in the monkish cell, and our ancient Universities do nothing to help us. The intolerant individuality which has enabled us to conquer and to govern where other nations have failed is of little use in an industrial war against the most systematically instructed people in the world, whose weapons are scientific research and scientific method, and who have been careful to "organise victory," to use Huxley's expression in his remarkable letter to the *Times* at the time that the proposal to establish the Imperial Institute was under discussion. Huxley warned us six years ago of the fate that awaited our industries if we did not organise victory. I fear that so far as chemistry is concerned our insular conservatism still leads us to turn a deaf ear to all such warnings, and that the only change is that we are six years nearer to our fate.

The following particulars are mainly taken from the number of the *Chemiker-Zeitung* above referred to. I am indebted to the Farbenfabriken, vormals F. Bayer and Co., for photographs from which the illustrations to this article have been prepared. I may add that I have had the very great pleasure of inspecting the laboratory.

The opening passage of the *Chemiker-Zeitung* notice is very significant, and is as follows :—

In any industry at the present day standing still involves retrogression, and this is especially the case in the colour industry, which has developed to such an extent in our country during recent years, and which owes its development in the first instance to the extreme attention paid to chemical science in Germany at the universities and technical schools. Whereas formerly, however, the colour industry owed its progress almost entirely to the schools and their celebrated leaders, of late years knowledge in this great field has become so specialised that a determining influence can be exercised only by one who is within the industry. Since the colour works have begun to pay attention to derivatives of coal and wood tar not only in the dyers' interest, but have also placed them at the service of medical science; and since it has been recognized that the protection afforded by a patent does not retard, but, on the contrary, promotes an industry, and is therefore to the general good, and patent laws have been introduced into Germany, of which, in comparison with those of other countries, we have reason to be proud, competition has so increased that all the works concerned are forced to make every effort to prevent their destruction in the struggle for existence. Consequently all the larger colour works within recent years have erected laboratories in which a large number of disciples of chemical science are unceasingly engaged in the endeavour to meet the growing wants of the dyer by adding to the already large number of artificial coal-tar colours, not only with the object of producing colours of increased beauty, but also to meet the growing desire for colours of greater fastness, and especially with the object of entirely displacing the natural dye stuffs which were formerly exclusively used. These technical laboratories are necessarily arranged with special reference to the requirements of the industry, and therefore differ in many respects from the laboratories at the universities and technical schools which are used for teaching purposes.

The laboratory of the Farbenfabriken, vormals Friedr. Bayer and Co. at Elberfeld, opened towards the close of 1891, is the newest institution of its kind.

Fig. 1 is from a photograph of the building taken from the street. The object in view was to provide all necessary rooms for twenty-six chemists. In order to make full use of the site, however, rooms for certain other purposes were also included. The laboratory adjoins the offices of the firm and the dye house, and also the physiological laboratory. The new building is 35·66 m. long and 16·14 m. deep.

A large portion of the basement is fitted up as a store for apparatus, &c., and is connected with the laboratories above by a stairway and lift. Luxurious provision is made here for the comfort of the staff, two rooms being provided in which they can change their clothes, along one side of each of which there are twelve clothes cupboards, and a bench with cupboards for boots underneath extending along the opposite side; and also of twelve separate bath rooms with hot and cold water, and a lavatory with twenty-four basins. The heating apparatus for the baths, and a low pressure steam heating apparatus, are placed next to the wall at one end of the building, and here also niches are constructed for autoclaves—*i.e.* vessels in which materials can be heated under pressure.

The ground floor is 6 m. high from floor to floor, excepting at the eastern end, where it is 1·28 m. deeper. The eastern higher portion is divided by a floor into two low apartments fitted up for experimental dyeing. Next to this and beyond the stairway on either side of a corridor are two rooms, 2·96 × 5·61 m., one of which is a combustion room, the other containing balances and other physical apparatus. The whole of the remaining space, 24·18 m. long by 14·6 m. deep, is fitted up as a laboratory for twelve chemists, and comprises twelve separate working places, and two for large operations for common use. This arrangement has the advantage that each chemist has had placed at his disposal a separate laboratory for his own use without the room having been deprived of its uniform character. Fig. 2 is from a photograph of the laboratory, Fig. 3 representing one working place.

The first floor includes a room 8·13 m. by 3·21 m. for the use of the director of the laboratory; a room 9·82 m. by 5·61 m. used as a library;[1] a room 5·61 m. by 2·96 m. for special use; and a large laboratory corresponding to that on the ground floor with places for thirteen chemists. A gallery carried on iron brackets is constructed along the side of this room on the outside of the building, in which experiments involving the production of specially unpleasant odours can be made. This gallery is approached through a glazed doorway constructed in one of the window places, but experiments going on in it can be overlooked from the laboratory within, through the windows.

The second floor is divided into two by a partition wall, one part being occupied by the printers engaged in preparing the various labels, notices, &c., required by the firm; the other being used by the bookbinders who make up sample-books, &c.

The attics are used as store rooms.

The building is simply constructed of brick, stone being used only for the window-sills; in fact, it is characterised throughout by simplicity and solidity of construction. The basement floor is cemented; the remaining floors are covered with antilaeolith, a clay asphalt which withstands hot strongly acid liquids.

The drainage water is carried away in open channels constructed in the floor.

The electric light is used throughout, the large laboratories being each illuminated by means of four arc lamps, and the other rooms by glow-lamps.

It has not been thought necessary to introduce any

[1] Probably there are few, *if any*, libraries attached to educational institutions so fully provided with the current literature and works of reference as are the libraries at the chief colour works.

FIG. 2.—Laboratory for twelve chemists, six on either side of main passage.

mechanical system to secure general ventilation. Air is admitted through openings in the upper part of the windows, the foul air finding sufficient means of escape up a shaft in which there is a spiral staircase, at the end of the large laboratories, and which terminates in a large opening in the western gable. Special care, however, is taken to remove fumes evolved in the chemical experiments. For this purpose a large number of earthenware pipes, 15 ccm. in diameter, are built into the walls between the windows in the large laboratories and elsewhere; these are carried up and connected with asphalted flues, which eventually terminate in a large air shaft carried out above the roof; the necessary draft is secured by means of a large fan placed at the base of the shaft, and driven by the engine in the printing department. At right angles to the walls at both sides of the rooms, between the windows, hollow walls are built out about 2·5 m., on either side of which draft closets are constructed (see Fig. 2), flue pipes such as have been referred to being let into these walls.

Passing over numerous interesting details of construction, the arrangement of the laboratories may now be referred to. Each place is so arranged as to constitute a complete laboratory with every necessary provision, while at the same time there is nothing to prevent the various chemists working together or to hinder the general supervision of the laboratory. The arrangement is best understood by reference to Figs. 2 and 3, of which the latter shows a single working place. The two side benches are connected by the window bench, so that each chemist has command of a bench about 15 m. long! The bottles on the shelves of each place contain 180 different agents—among these being all the substances in use or produced in the works, so that, if desired, any combinations tried in the laboratory may at once be effected on the large scale in the works. The pipes for gas, water, compressed air and vacuum are carried in a space behind the shelving, and can be easily got at for repairs, the shelving being made removable. The benches, except at the windows, are covered with lead. Under the bench there are numerous drawers and cupboards, containing all apparatus that can possibly be required, and also chemicals such as salt, potassium chloride, sodium acetate, &c., which are used in large quantities. Thus in Fig. 3 a sliding stand will be seen projecting from a cupboard on the right-hand side, carrying measuring cylinders inverted over pegs. Each drawer or cupboard, in fact, has its special purpose, and is carefully labelled, the same arrangement being maintained throughout the laboratory, so that the attendants are able to see that each chemist is supplied with all necessary apparatus. On either bench next the window there is a closed draft-closet, and next to it a hood, it being possible to connect these by a moveable window. In one of the closets there is a large copper water bath, in which steam, previously cleaned from rust, condenses and can be drawn off as boiling distilled water; this bath has the usual openings above with rings, &c., and has within it a drying oven surrounded by boiling water, a wooden drying closet being placed below in which things can be dried by heat radiated from the water bath above. The waste water and steam pass away through the hollow wall at the back of the closet, in which there is a channel communicating with the drain.

FIG. 3.—Working place of one chemist.

On either side of the window a pipe connected to the general ventilation system is let into the wall, to which a funnel-shaped hood can be attached, so that experiments involving the evolution of fumes can be carried on at the window-bench. This bench, however, is chiefly used for titration work, and therefore shelves are affixed to the wall some distance above it on either side, on which large bottles are placed containing the standard solutions.

It will be seen from Figs. 2 and 3 that a sink is placed at the end of the bench on the one side, and that there is a desk on the opposite side; adjoining this desk is an ice cupboard let into the bench, on the cover of which a balance for weighing out substances used in the experiments is placed. By the provision of such an ice cupboard at every place a great saving of ice has been effected: it is not only available for the storage of ice—nowadays an indispensable laboratory agent—but things can be kept cool in it even over long periods, over Sunday for example.

Four differently coloured pipes for water, gas, compressed air and vacuum run along the ceiling, and from these branch pipes are carried down the columns to the benches; taps are provided in a convenient situation, so that, if necessary, the supply of water, &c., to a bench may be at once shut off. The water pipes are covered with flannel to prevent the water which condenses on them from dropping down. Each working place is provided with 4 taps for compressed air, 4 vacuum taps, 11 water taps, 14 gas taps for heating purposes, and 9 gas burners in case of a failure of the electric light. A steam pipe runs along the wall, from which there are branch pipes connected with "purifiers," conveying steam to each of the large water baths before referred to, and to a valve under the hood adjoining the closet.

A shower bath depends from the ceiling at either end of each of the large laboratories for use in case of the clothes of any of the chemists or laboratory attendants catching fire.

Every bottle on the shelves is not only clearly labelled, but is also numbered, so that it is easy for the lad who has to keep the place clean and in order, however ignorant he may be, to arrange them properly, and moreover, each particular chemical occupies the same position in the row of bottles in every place in the laboratory.

Each chemist has a lad to assist him who washes all vessels, keeps the benches clean and the apparatus in order; in fact, does generally what he is told, even helping in the experiments. In addition, there are three lads under the supervision of an older laboratory servant in each laboratory, who at once avail themselves of any opportunity offered by the absence of the staff to "tidy up" in regions not specially committed to the charge of the young assistants. The order and cleanliness—extending even to keeping the leaden bench tops polished—thus secured is most remarkable.

Each chemist is so completely screened from his neighbour "next door," that he is not only able to work undisturbed, but practically in secret; he is only open to observation from the place on the opposite side of the main gangway, and the chemists are usually so placed that of the two working at these benches either the one is a junior under the direction of the other, or they are working in co-operation.

As a further illustration of the perfection of the arrangements I may quote from an account before me of a visit to the laboratory a description of the steps taken to put out a fire. A crack is suddenly heard and flames and a dense cloud of smoke are seen to ascend from one of the benches; all the chemists in the room at once rush to the spot. The particular chemist is found to be unhurt, but the clothes of his laboratory boy are on fire; instantly he is dragged to the shower bath, and the fire is at once put out. Meanwhile the laboratory servant has given the alarm by means of the electric fire alarm provided in the room, and within two minutes the twelve men on duty of the twenty-four members of the works fire brigade appear in full uniform. Those present, however, by turning on all the water taps in the neighbourhood of the fire and directing the water on to the burning bench had already extinguished the flames. The room is filled with a dense black fog, but by opening the windows and a valve in the main ventilation system near the ceiling this is very soon got rid of. The origin of the accident was simple enough: a young chemist, fresh from the University, unaccustomed to work with large quantities, had allowed his laboratory boy to heat a couple of litres of the hydrocarbon toluene, which he was using in recrystallising a substance, in a glass flask, over a bare flame.

Another striking feature in the large laboratories is a series of brass valves arranged along the wall under a hood opposite the bench for general use; the labels under these valves bear the names oxygen, carbon dioxide, chlorine, sulphur dioxide, phosgene, methyl chloride, hydrogen and ammonia. These various gases, compressed in cylinders enclosed in cupboards in the basement, can be used at any time by communicating through a speaking tube to the man in charge of the store department, who then opens the valve on the cylinder containing the required gas, so that it only remains for the chemist to open the valve in the laboratory.

In the lower laboratory one place only is distinguished from all the others, being fitted up for electro-chemical work with the necessary current-measuring instruments, a series of about fifty glow lamps being arranged as resistances.

In the balance-room, besides balances, there is a large arc lamp with special lenses designed by Prof. von Perger, of Vienna, used in ascertaining the effect of light on colours—in these days sunlight can no longer satisfy the needs of German industrial enterprise! Colorimeters, spectroscopes, and other apparatus are also to be found in this room. Colour chemists are not fond of making analyses if it be possible to characterise substances by any other means; the combustion furnaces are therefore but little used, and a number of ovens in which pressure tubes are heated have supplanted most of them.

Adjoining the research laboratories there is a "technical laboratory" full of apparatus exactly like that in use in the works, but of much smaller size. Here experiments are carried out on a somewhat larger scale than in the laboratory prior to the processes being effected on the large scale in the works; and the staff in this laboratory are also engaged in making many of the chemicals required to replenish the stores for use in the research laboratories.

The stores are in charge of two superintendents, one of whom is educated as a glass-blower. It is worth mentioning also that all thermometers, prior to their issue from the store, are there compared with a normal thermometer.

The laboratory was designed by my friend Dr. C. Duisberg, the director, the necessary architectural assistance being afforded by Herr Bormann, architect to the works.

The foregoing is but a very imperfect account of this marvellous works research laboratory. A more typical and concrete illustration of the appreciation of the value of science by German manufacturers, however, could not possibly be found, but yet it is only one of many that might be brought forward. Personally I can only say, that while lamenting the criminal short-sightedness of my countrymen, I am lost in admiration of the enterprise displayed by their foreign competitors: it cannot be denied that they deserve to succeed!

HENRY E. ARMSTRONG.

ELECTRO-OPTICS.

THE experimental and theoretical investigations of the last twenty years have lent a new interest to what, I venture to think, is one of the most fascinating branches of physical optics, namely, the action of an electromagnetic field upon light. The discoveries which have hitherto been made may be classified under four heads: (1) Faraday's experiments, which show that when plane polarised light is transmitted through a *transparent* magnetised medium, a rotation of the plane of polarisation is produced; (2) Kerr's experiments, which show that the effect of electrostatic force on a *transparent* medium is to convert it into one which is optically equivalent to a uniaxal crystal whose axis is in the direction of the force; (3) Kerr's experiments on the reflection of plane polarised light at the surface of a magnetised iron reflector, which show that a rotation of the plane of polarisation of the reflected light takes place, which in certain cases is in the same and in others in the contrary direction to that of the amperean current which may be conceived to produce the magnetic force; (4) Kundt's experiments on the reflection of light from magnetised iron, cobalt, and nickel, and also on the transmission of light through thin magnetised films of these metals. There is also another series of experiments by Kundt, in which polarised light is refracted at the upper surface of a plate of glass, is then reflected at the lower surface, and again refracted at the upper surface. The results of these experiments show that the plane of polarisation of the ultimately emergent light is rotated in the *contrary* direction to that produced by an iron reflector.

There seems to be a fair amount of evidence to lead to the conclusion that Hall's effect is intimately connected with the action of a magnetic field upon light, but further evidence is required before it can be asserted that both phenomena are due to the same ultimate cause. Up to the present time Hall's effect has, I believe, only been detected in conducting media; but if it be assumed to be capable of existing in transparent media, theory furnishes results which, as far as they have been worked out, are in agreement with experiment. Hall's effect is capable of explaining the experiments of Faraday, and it also gives a result in accordance with Kundt's experiments on reflection and refraction from a plate of magnetised glass in the case in which the magnetisation and incidence are normal. It would be quite possible to apply this theory to the case of oblique incidence, but the work would be laborious and the final results complicated. The experiments of Prof. Dewar on liquid oxygen would seem to provide a more promising way of testing this theory, for, on account of the high susceptibility of this substance to magnetic action, it is possible that an effect might be observed in the case of *direct* reflection.[1] According to theory, Hall's effect ought to be positive in the case of glass and gaseous oxygen, and negative in the case of a solution of perchloride of iron; and a repetition of Kundt's experiments, in which the latter liquid is employed in the place of glass, ought to show that the rotation takes place in the *same* direction as that produced by metallic iron. Such experiments would be valuable as a further test of the theory, but they do not appear to have been made.

A paper recently communicated to the Cambridge Philosophical Society (May 1) still further confirms the view which I have put forward. In this paper I have transformed the formulæ for reflection at a magnetised *transparent* medium by assuming that the refractive index is a complex quantity. The resulting formulæ for the amplitudes of the reflected vibrations agree very well with Kerr's experiments so far as qualitative results are concerned, provided the values and signs of certain quantities are supposed to be determined by optical, as distinguished from electromagnetic methods. They are, moreover, the same *as regards their form* as those deducible from Maxwell's theory by taking into account the conductivity combined with Hall's effect; but unfortunately the values of certain constants, when expressed in terms of electrical quantities, differ from the values which are required by optical experiments, in a manner which prevents a perfectly satisfactory electromagnetic theory being constructed in this way, and I doubt whether it will be possible to attain the end in view until a theory based upon the mutual reaction of ether and matter has been discovered in which quantities, upon which the motion of matter depends, enter into combination with electromagnetic quantities.

Although the sign of Kerr's effect in nickel is the same as in iron and cobalt, the sign of Hall's effect is different. This difficulty is apparent rather than real, for a theory based upon the mutual reaction of ether and matter might very well introduce a factor containing the free periods of the vibrations of the matter which would change the sign of the magnetic terms. Some light might be thrown on this point by determining the principal incidence and azimuth for nickel and cobalt.

The generally received theory, that reflection and refraction are materially influenced when any of the free periods of the vibrations of the matter fall within the limits of the visible spectrum, suggests that the sign of Kerr's effect may be different in the case of the ultra-violet and the infra-red portions of the spectrum from what it is in the luminous portion. Experiments on this branch of the subject are needed, and possibly the employment of a fluorescent substance, such as quinine, in the case of the ultra-violet waves, or of a solution of iodine in disulphide of carbon, in conjunction with Prof. Langley's bolometer,[2] when the infra-red waves are experimented upon, might furnish important information on this point.

The experiments of Kerr on the effect of electrostatic force suggest that if light were reflected from a strongly electrified metallic conductor, certain peculiarities would be observed. In the absence of experiments, which do not appear to have been made, it would be impossible to predict with certainty what these effects are likely to be; but it would seem probable that an electrified metallic reflector would behave like a doubly-refracting metallic medium having a *single* optic axis which is perpendicular to the reflecting surface. When light is reflected from the surface of a uniaxal crystal which is cut perpendicularly to the axis, the component vibration at right angles to the plane of incidence is reflected in the same manner as if the medium were isotropic. Under these circumstances we should anticipate that in the case of an electrified metallic reflector, the component vibration *in* the plane of incidence would be much more strongly affected by electrification than the component at right angles to this plane. If this speculation should be verified by experiment, it would follow that the principal incidence and azimuth, and also the difference between the changes of phase of the two components, would be affected by electrification in a manner which could be observed.

In conclusion I would point out that further experiments are required of the following nature:—

(1) Experiments on the reflection of light from magnetised *transparent* media, such as glass, perchloride of iron, and also if possible from liquid oxygen.

(2) Experiments on reflection from and transmission through magnetised metals, special attention being paid to the effects produced by the non-luminous portion of the spectrum.

(3) Experiments on reflection from *electrified* metallic reflectors.

A. B. BASSET.

[1] The effect produced by a *single* reflection from magnetised glass would be too feeble to be detected; but Dr. Kerr suggested to me that an effect might possibly be observed by employing the method of multiple reflections.

[2] I do not know whether the bolometer is more sensitive to heat than a pair of average eyes are to light; if it is, experiments on the infra-red waves ought to be easier than experiments on luminous waves.

NOTES.

The annual meeting of the Iron and Steel Institute will be held at the Institution of Civil Engineers, 25, Great George Street, London, on Wednesday and Thursday, May 24 and 25. On Wednesday business will be transacted; the Bessemer Gold Medal for 1893 will be presented to Mr. John Fritz, of Bethlehem, Pa., U.S.A.; and the president-elect, Mr. E. Windsor Richards, will deliver his inaugural address. The following papers will afterwards be read and discussed: "On the elimination of sulphur from iron and steel" (second paper), by J. E. Stead; "On the Saniter process of desulphurisation," by E. H. Saniter. On Thursday the following papers will be read and discussed:—"On the basic process of Witkowitz," by F. Kupelwieser; "Notes on puddling iron," by John Head; "On a recording pyrometer," by Prof. Roberts-Austen, F.R.S.

The Royal Society *soirée* was being held as Nature went to press yesterday evening.

A dinner will be given by the Master and Fellows of Gonville and Caius College, Cambridge, on Wednesday, June 21, in the College Hall, to celebrate the tercentenary of the admission of William Harvey to the college.

The annual dinner of the Royal Geographical Society will take place on Saturday, May 13, at the Whitehall Rooms, Hôtel Métropole, Sir M. E. Grant Duff, President of the Society, in the chair.

The second annual Robert Boyle Lecture of the Oxford University Junior Scientific Club will be delivered in the University Museum on Tuesday, the 16th inst., at 8.30 p.m., by Lord Kelvin, P.R.S. His subject will be, "The Molecular Tactics of Crystals."

The Geologists' Association has made arrangements for a geological excursion to Farnham on Saturday, May 13. During Whitsuntide there will be an excursion to Bradford-on-Avon and Westbury, in Wiltshire.

The late Lord Derby has left by will to the Royal Society a sum of £2000. He has also bequeathed £2000 to the Royal Institution.

The Royal Society of New South Wales offers its medal and £25 for the best communication sent in not later than May 1, 1894, containing the results of original research or observation upon each of the following subjects:—(1) On the timbers of New South Wales, with special reference to their fitness for use in construction, manufactures, and other similar purposes; (2) on the raised sea-beaches and kitchen middens on the coast of New South Wales; (3) on the aboriginal rock-carvings and paintings in New South Wales.

The Royal Hungarian Academy of Sciences at Buda-Pesth has devoted the sum of 2000 fl. to the promotion of botanical investigations during the year 1893.

The Committee of the Kew Observatory has issued its report for the year ending December 31, 1892.

The Council of the Durham College of Science has resolved to offer to each county council in England the right of nominating a scholar who shall attend the course of instruction in the agricultural department of the college without the payment of fees, on condition that the county council pay to the scholar not less than £30 towards the cost of his board and lodging in Newcastle or the neighbourhood, and of such books or appliances as he may require for his study. The scholarships will be tenable in the first instance for one year, but may be renewed for a second year by the college council if the progress o the student is satisfactory. The object of the college council is twofold: to bring before the notice of county councils and others the advantages offered by its agricultural department, and to make some acknowledgment to the country generally for the contributions it has received from imperial sources through the Board of Agriculture.

The Yorkshire Naturalists' Union is making a great effort to double its membership, and ought to have little difficulty in accomplishing its purpose, as it is one of the most vigorous of the provincial scientific societies. Its funds are at present insufficient to justify it in publishing all the important works it has in hand.

Mr. M. A. Veeder writes to us from Lyons, New York, that Lieut. Peary, of the United States Navy, during his coming expedition to the northernmost Greenland, will record observations of the aurora, upon a plan that will enable comparisons to be made in detail with records from other localities. "The plan," Mr. Veeder says, "is already in operation, upon an international basis, and the results are proving to be important. Numerous observers widely distributed are desirable, and inasmuch as even those who have no special technical knowledge may make entries that will be of value any who feel so disposed may co-operate." Further information and supplies of blanks may be obtained from Mr. Veeder, who will be glad to receive also, any records of observations of the aurora whatever, for purposes of comparison.

Moderate rains occurred in the north and west, in the early part of last week, owing to the advance of depressions from the Atlantic, and a small amount of rain fell in the midland counties, but over the southern and eastern parts of England there was no measurable quantity. The drought has continued with great persistency over the southern part of the kingdom, the period without rain, up to Tuesday the 9th inst., being fifty-three days at some of the stations reporting to the Meteorological Office. An anticyclone embraced the greater part of western Europe throughout the past week, and spread westwards over the British Islands, causing high atmospheric pressure, while in northern Scandinavia the barometer rose to nearly 31 inches. The temperature has been irregular; although high for the time of year, it has been lower generally than some weeks ago; in a few instances the daily maxima have exceeded 70°, but in parts they have been little above 50°. The *Weekly Weather Report* of the 6th instant showed a general decrease of bright sunshine. The percentage of possible duration ranged from 18 to 27 in Ireland, from 22 to 30 in Scotland, and from 41 to 57 in England; in the Channel Islands the high percentage of 81 was recorded.

At the meeting of the French Meteorological Society on April 4 Dr. Fines presented a note on the violence of the storms which are occasionally experienced in the province of Roussillon (Eastern Pyrenees). On five occasions between 1860 and 1867 railway trains have been overturned on the line from Narbonne to Perpignan. A storm of great violence occurred from January 15 to 24 last, in which at one time the velocity amounted to 85 miles an hour. A large number of trees were uprooted and some loaded railway trucks were overturned on this occasion.

The annual general meeting and *conversazione* of the Selborne Society were held at the rooms of the Royal Society of British Artists yesterday evening. The objects of this excellent society are: to preserve from unnecessary destruction such wild birds, animals, and plants as are harmless, beautiful, or rare; to discourage the wearing and use for ornament of birds and their plumage, except when the birds are killed for food or reared for their plumage; to protect places and objects of interest or natural beauty from ill-treatment or destruction; and to promote the study of natural history. Many good writers on natural history contribute to the society's journal, *Nature Notes*.

A CAPITAL paper on the manufactures of India was read by Sir Juland Danvers before the Indian Section of the Society of Arts on April 24, and is published in the current number of the Society's Journal. Sir Juland is of opinion that, if all legitimate means are taken for opening the markets of the world to Indian commerce and for stimulating enterprise and energy by developing the country itself, India may become a large manufacturing as well as an agricultural country, and thus be enabled not only to support but to improve the condition of her vast population. The reading of the paper was followed by a most interesting discussion, in the course of which several high authorities expressed their cordial agreement with the views stated by Sir Juland Danvers. Sir C. E. Bernard said that short of vast discoveries of workable gold within her borders India's true and only way out of the silver difficulty that threatens her with bankruptcy is the rapid development of her home industries, especially her cotton and iron manufactures.

THE Trinidad Field Naturalists' Club prints in its Journal for April a valuable preliminary list of the mammals of Trinidad, by Mr. Oldfield Thomas, of the British Museum (Natural History). Mr. Thomas explains that he has prepared the list as a basis on which a complete scientific list of the mammals inhabiting Trinidad may be founded, and to show members of the society how extraordinarily little is definitely known of the mammals of the island. By known, of course, he means scientifically known in the sense of being published to the world, for he has no doubt whatever that many members of the society could off-hand add to the list many animals well-known to them and other inhabitants, but neither hitherto mentioned in scientific publications nor represented by specimens in the British Museum. He earnestly begs that all persons interested in the natural history of Trinidad will do what they can to obtain specimens and to send them home for identification. Every collection made at present is sure, he says, to contain species new to the island, even if not—as in the case of two bats recently received from Trinidad—altogether new to science.

A PAPER on "Recreation," read by Mr. William Odell before the Torquay Natural History Society, has been printed separately. It contains some very interesting letters from the head masters of public schools as to the effect of athletics on school work.

MR. FREDERICK J. HANBURY and the Rev. E. S. Marshall are engaged in the preparation of a Flora of Kent, which should prove an exceptionally rich county flora, though some districts have as yet been but imperfectly searched. Any assistance will be gladly received by the Rev. E. S. Marshall, Milford Vicarage, Godalming.

MR. A. T. DRUMMOND has been investigating the colours of flowers in Ontario and Quebec in relation to the time of flowering, and has contributed to the *Canadian Record of Science* an interesting paper on the subject. He finds that April, May, and even June and July are remarkable for the prevalence of white flowers, July and especially August of yellow, and September and October of purple and blue.

GOOD illustrations of the difficulty of determining plants or vegetable productions by popular or local names are given in a letter by Mr. B. B. Smyth, of the Kansas Academy of Science, published in the current Quarterly Record of the Royal Botanic Society of London. "The name Nightshade," he says, "is applied here to *Solanum nigrum* and *S. triflorum*; the name Woody Nightshade is applied to *S. Dulcamara*; the name Bittersweet is applied to *Celastrus scandens*, a twining woody plant with clusters of showy scarlet berries; the name Laurel is applied to the different species of Kalmia; the names Mock Orange and Syringa are applied (of course misapplied) to Philadelphus; the name Sarsaparilla is (mis)applied to Aralia; the name Snakeroot is applied to a dozen different species in half as many different orders; the name Mouse-ear is applied to Gnaphalium, Antennaria, and Cerastium."

WE have repeatedly called attention to the fact that the German publisher Engelmann is issuing an important series of small volumes consisting of papers which have marked an era in the history of science. A series of much the same kind has been begun, we are glad to note, by Mr. W. F. Clay, Edinburgh, and Messrs. Simpkin, Marshall and Co., London. The volumes in this series are to be known as "Alembic Club Reprints.' The first volume consists of Joseph Black's paper, entitled, "Experiments upon Magnesia Alba Quicklime, and other Alcaline Substances."

THE Natural History Society of Marlborough College has issued its report for the year ending Christmas, 1892. The high standard of work in the sections is said to have been, on the whole, well maintained; but an exception is made in the case of the zoological section, the members of which showed "little disposition to exert themselves in work conducted on scientific lines." The library of the society is rapidly increasing. Among the works added to it during the year were the four splendidly illustrated volumes (privately printed) on excavations and archæological discoveries in or near Wilts, by General Pitt-Rivers. These were presented by the author, to whom special thanks are accorded for his "peculiarly interesting and valuable gift."

ARISTOTLE, it seems, knew almost as much about field voles as is known by those who have lately been studying the mischief done by these creatures in Thessaly and Scotland. In a passage quoted in the current number of the *Zoologist* from his "Natural History of Animals" he speaks of their power of destruction as "so great that some small farmers, having on one day observed that their corn was ready for harvest, when they went the following day to cut their corn, found it all eaten." "The manner of their disappearance also," he continues, "is unaccountable; for in a few days they all vanish, although beforehand they could not be exterminated by smoking and digging them out, nor by hunting them and turning swine among them to root up their runs. Foxes also hunt them out, and wild weasels are very ready to destroy them; but they cannot prevail over their numbers and the rapidity of their increase, nor indeed can anything prevail over them but rain, and when this comes they disappear very soon." This passage is quoted in the *Zoologist* by Mr. A. H. Macpherson. The editor adds a note showing that Aristotle was by no means the only ancient writer to whom the facts were familiar.

MR. G. LEWIS contributes to the current number of the *Entomologist* a list of coleoptera new to the fauna of Japan, with notices of unrecorded synonyms. Some of the list are well-known European species; others have hitherto been known from Siberia only. Mr. Lewis says that some years will elapse before the collection gathered by him in Japan can be completely worked out.

AN interesting paper on mining and ore-treatment at Broken Hill, New South Wales, was read at the meeting of the Institution of Civil Engineers on May 2, the authors being Mr. M. B. Jamieson and Mr. J. Howell. From this mine silver and lead of the value of over £8,250,000 sterling had been taken within seven years; and it continued to yield about

220,000 ounces of silver, and between 600 and 800 tons of lead per week. Speaking of the products of the refinery, the authors said they were thus disposed of:—The pure silver was sold in the colonies by tender at stated intervals, in parcels of between 100,000 ounces and 150,000 ounces, and was purchased by the banks usually at a price somewhat above the price current in London. The soft lead was shipped either to England or to China; the latter country was becoming gradually a larger buyer of the company's lead. The matte and other compound products were shipped to England. The small amount of gold in the ore was recovered in the refinery. It amounted to about 3·4 dwt. per ton of bullion.

Mr. C. Hedley has contributed to the Proceedings of the Linnean Society of New South Wales (Second Series, vol. vii.) an interesting paper on the range of *Placostylus*, which he describes as a more fruitful subject of study than any other molluscan genus inhabiting the same area. Their large and handsome shells have attracted the attention of the most superficial and unscientific collectors, so that an extensive series has been brought to the knowledge of investigators from remote localities. In the summary of his results, Mr. Hedley remarks, first, on the essential unity of the *Placostylus* area as a zoological province, embracing the archipelagoes of Solomon, Fiji, New Hebrides, Loyalty, New Caledonia, Norfolk I. (?), Lord Howe, and New Zealand; a unity explicable, he thinks, only on the theory that they form portions of a shattered continent and are connected by shallow banks formerly dry land. This continental area he proposes to call the Melanesian plateau. He holds, secondly, that this Melanesian plateau was never connected with, nor populated from, Australia, but that its fauna was probably derived from Papua *viâ* New Britain. The presence of genera common to Australia and New Zealand he believes to be explicable on the ground that they migrated, not from the one territory to the other, but each from a common source, New Guinea. Thirdly, he thinks that New Zealand and New Caledonia were early separated from the northern archipelagoes and ceased to receive overland immigrants therefrom. Fourthly, the Fijis, according to Mr. Hedley, remained to a later date in communication with the Solomons, but were severed from that group before the latter had acquired from Papua much of its present fauna.

The "Year Book of Australia" for 1893 has been published. It includes an interesting account of scientific work done in the various Australian colonies during 1892. This has been compiled from information supplied by the scientific societies of Australia.

Some valuable reports on the Victorian coalfields, by Mr. James Stirling, of the Geological Survey of Victoria, have been issued by the Department of Mines in that colony. They are fully and most carefully illustrated.

A French translation of Lord Kelvin's "Popular Lectures and Addresses" has been published by Messrs. Gauthier-Villars et Fils. The translator is P. Lugol, who has added some notes. Translations of extracts from recent memoirs by Lord Kelvin, with notes, have been contributed by M. Brillouin.

A fresh instalment of the Proceedings of the American Academy of Arts and Sciences (New Series, vol. xix.) has just been published. It covers the period from May 1891 to May 1892. Among the contents are some considerations regarding Helmholtz's theory of consonance, by C. R. Cross and H. M. Goodwin; a note on the dependence of viscosity on pressure and temperature, by C. Barus; what electricity is: illustrated by some new experiments, by W. W. Jacques; on a theorem of Sylvester's relating to non-degenerate matrices, by H. Taber; researches on the volatile hydrocarbons, by C. M. Warren; descriptions of new plants collected in Mexico by C. G. Pringle in 1890 and 1891, with notes upon a few other species, by B. L. Robinson; on some experiments with the phonograph, relating to the vowel theory of Helmholtz, by C. R. Cross and G. V. Wendell, and other papers.

A paper entitled "Further Studies of Yuccas and their Pollination" has been contributed by Mr. W. Trelease to the fourth annual report of the Missouri Botanical Garden, and is also published separately. It is well illustrated.

The new number of the *Quarterly Journal of the Geological Society* includes the text of the anniversary address of the President, Mr. W. H. Hudleston, F.R.S. He deals with the work brought before the Society in the course of the last seven years, during which he has served the Society in one official capacity or another.

A fourth edition of "Practical Physics," by R. T. Glazebrook and W. N. Shaw, has been issued by Messrs. Longmans, Green, and Co. The authors have taken advantage of this opportunity to make some alterations and additions suggested by their own experience or that of their successors at the Cavendish Laboratory.

In a recent number of the *Comptes Rendus*, M. Rigollot gives a further account of his experiments on the electrochemical actinometer. He finds that the electromotive force developed when light falls on a plate of oxydised copper immersed in a solution of a metallic iodide, bromide or chloride can be considerably increased if it has previously been dipped in some colouring matter, such as eosine or safranine. This increase of sensitiveness is different for rays of different wave lengths, and those rays which produce the maximum effect, for any one colouring substance, depend on the position of the absorption band in the light which is transmitted by that substance.

M. Chassagny has a note in the current number of the *Comptes Rendus* on the influence of longitudinal magnetisation on the electromotive force of an iron-copper thermo-electric junction. Two couples were used, one being in the axis of a long magnetising helix, so joined together that they acted in opposite directions. The results obtained were:—(1) The effect of longitudinal magnetisation is always to increase the electromotive force. (2) This increase is independent of the direction of magnetisation. (3) For increasing fields the increase is at first very nearly proportional to the strength of the field, and attains a maximum value of 6·1 microvolts for a field of 55 C.G.S. units. After this it slowly decreases till for a field of 200 units it is 3·2 microvolts.

At the meeting of the Société Française de Physique, held on April 21, M. P. Curie gave some of the results of his experiments on the magnetic properties of bodies at different temperatures. The body to be experimented on was placed in a non-uniform magnetic field and the force acting on it measured by the torsion of a metallic wire. An electric heater capable of raising the temperature of the body to 1400° C. was used, together with one of Le Chatelier's thermo-elements to measure the temperature. In the case of oxygen, the magnetic permeability is constant for magnetising forces of from 200 to 1350 units, and for pressures of from 5 to 20 atmospheres. The law of variation of the permeability with temperature is very simple, since between 20° and 450° it varies inversely as the absolute temperature. In the case of air, the permeability at a temperature t is given by the formula $10^6\mu_t = 2760/t^2$, which can be used to correct observations made in air at any temperature.

A NEW reaction, of wide general application and of considerable practical utility, by means of which the important organic compounds known as nitriles may be readily prepared in a state of purity, has been discovered by Prof. Michaelis and Dr. Siebert, and is described by them in the current number of *Liebig's Annalen*. As stated in our chemical note of last week, Prof. Michaelis has recently been studying the action of thionyl chloride, $SOCl_2$, upon the primary amines, and has shown that the product of the reaction is a thionylamine, a compound formed by the replacement of the two hydrogen atoms of the NH_2 group of the amine by the radical thionyl, SO. In seeking to ascertain whether a similar kind of compound to the thionylamines is formed when thionyl chloride is allowed to act upon the amides of the acid radicles, Prof. Michaelis and Dr. Siebert have discovered the new mode of preparing the nitriles. Instead of a compound of such a nature being produced, a nitrile is the main product, with sulphur dioxide and hydrochloric acid as bye products. As the two latter are gaseous substances, it is at once evident that the reaction must afford a particularly convenient mode of preparing the nitriles in a state of purity. The reaction, moreover, is quite general, and is applicable both in the fatty and in the aromatic series. When thionyl chloride is brought in contact with acetamide, $CH_3 . CO . NH_2$, a violent reaction occurs, with considerable rise of temperature. After a few minutes, however, the violence diminishes, and the liquid eventually becomes quiescent. In order to complete the interaction, the product should then be heated over a water-bath for a few hours, the reaction flask being provided with a reflux condenser. When the fumes of hydrochloric acid and the odour of sulphur dioxide are no longer perceptible, the reaction is completed in accordance with the equation—

$$CH_3 . CO . NH_2 + SOCl_2 = CH_3 . CN + SO_2 + 2HCl.$$

The dark-coloured liquid is then decanted from a small quantity of resinous products of decomposition and distilled, when pure acetonitrile, clear and colourless, passes over it at its boiling point, 82°. The yield of pure nitrile is about half the weight of acetamide employed. The violence of the reaction between thionyl chloride and acetamide is very much diminished by the addition of benzene; but owing to the difficulty of separating the resulting nitrile from the benzene by fractional distillation, it is preferable not to employ it. With care, the direct addition of the thionyl chloride may be made without loss. Propionamide reacts in a very similar manner with thionyl chloride, and almost the whole of the liquid product distils over quite colourless at the boiling point of propionitrile (98°). In like manner, pure benzonitrile may be obtained by the action of thionyl chloride upon the amide of benzoic acid. It is preferable, however, in case of such higher boiling nitriles which can be readily separated from benzene by fractional distillation, to conduct the operation in presence of benzene, the reaction then proceeding much more regularly and without the violence of the direct action. Upon subsequent distillation, the thermometer at once rises to 190° after the distillation of the benzene, and remains constant at that temperature until almost the whole of the benzonitrile has passed over.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include the Hydroid *Hydractinia echinata*, the Polychæta *Eunice Harassii* and *Siphonostoma uncinatum*, the Polyzoan *Pedicellina cernua*, the Opisthobranchs *Runcina coronata* and *Polycera Lessonii*, the Crustacean *Hyas araneus*, and the Echinoderms *Cucumaria Planci* and *Luidia ciliaris*. The quantity of gelatinous algæ in the Channel waters at length exhibits signs of diminution. Medusæ of the remarkable Hydroid *Corymorpha nutans* (of Allman) have been taken in the tow-nets on several occasions. The medusæ of *Aurelia aurita* are growing rapidly in size, and have now attained an average diameter of 1¼ inches. The *Megalopæ* of *Carcinus* are no longer commonly taken in the tow-nets, but are chiefly to be found in especial haunts at the sea-bottom. The following animals, not hitherto noted, are now breeding: the Hydroids *Plumularia setacea* and *Antennularia ramosa*, the Decapod Crustacea *Crangon fasciatus* and *Hippolyte Cranchii*, the Ophiurid *Amphiura elegans* (= *squamata*), the Ascidian *Styelopsis grossularia*, and several species of Amphipoda and Pantopoda.

THE additions to the Zoological Society's Gardens during the past week include two Mozambique Monkeys (*Cercopithecus pygerythrus*, ♀ ♀) from East Africa, presented respectively by Mr. Arthur James and Miss Maude Parkinson; a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Miss G. Lloyd; a Bonnet Monkey (*Macacus sinicus*, ♀) from India, presented by Mr. R. Hughes; a Macaque Monkey (*Macacus cynomolgus*, ♀) from India, presented by Mr. F. Byfield; an Indian Buffalo (*Bubalus buffelus*, ♀) from India, presented by H.H. The Maharaja of Bhoonagar; a Common Hedgehog (*Erinaceus europæus*) British, presented by Mrs. E. Austen-Leigh; a West African Love-Bird (*Agapornis pullaria*) from West Africa, presented by Lady Theodora Guest; two Herring Gulls (*Larus argentatus*) British, presented by Mr. W. H. Aplin; two Egyptian Mastigures (*Uromastix spinipes*) from Egypt, presented by Mr. Edmund Lamb; a Moorish Tortoise (*Testudo mauritanica*) from North Africa, presented by Mr. T. W. Bayley; seven Green Tree Frogs (*Hyla arborea*) South European, presented by the Rev. C. D. Fothergill; a Silvery Gibbon (*Hylobates leuciscus*) from Malacca, a Roseate Cockatoo (*Cacatua roseicapilla*) from Australia, twenty Green Tree Frogs (*Hyla arborea*) South European, deposited; two Amherst Pheasants (*Thaumalea amherstiæ*, ♀ ♀) from Szechuen, China, a Swinhoe's Pheasant (*Euplocamus swinhoii*, ♂) from Formosa, three Cat Fish (*Amiurus catus*) from North America, purchased; a Common Crowned Pigeon (*Goura coronata*) from New Guinea, received in exchange; a Yak (*Poëphagus grunniens*), ♀), a Water Buck (*Cobus ellipsiprymnus*, ×), an Angora Goat (*Capra hircus. var.* ♂,), a Bennett's Wallaby (*Halmaturus bennetti*, ♂) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

MERIDIAN CIRCLE OBSERVATIONS.—At the meeting of the Royal Astronomical Society, held on April 14 last, the proceedings of which are recorded in the current number (No. 201) of the *Observatory*, the paper prepared by Messrs. Turner and Hollis (and read by the former) entitled, "Comparison of the Greenwich Ten-year Catalogue (1880) with the Cape Catalogue (1880)," was the means of instigating an interesting discussion with reference to questions relating to systematic error of meridian observations. The questions thus raised are of great importance, for, as Dr. Gill remarks, they "affect the objects for which public observatories were founded." Generally speaking the comparison of the catalogues above mentioned seems to have given very satisfactory results, but the series of differences obtained from the north-polar-distances, arranged in order of north polar distance, showed signs of small divergences. The source from which these differences could have arisen seems—since the accuracy of the N.P.D. places depends on the coefficient of refraction—to be at first sight apparent, and Mr. Stone's opinion is that this quantity is "practically mixed up with the question of refraction," his firm conviction being that in the Cape observations there are no systematic errors possible to account for 0″·4. Dr. Gill, in referring to the discussion generally, made some very striking remarks about meridian observations, and was of opinion that at the Cape there were sources of systematic error amounting possibly to half a second of arc. The differences obtained from the reflex and direct observations at the Cape, he says, have led him to the conclusion that they are caused by the fact that, "since the walls of the transit room are about three feet thick, they retain for a long time the heat which they absorb during the day. The result is that there are layers of air of different temperature in the room at night." To improve fundamental astronomy, half a second of arc, he says, must be seriously taken into account, and this can only be done by employing a sound instrument and a properly-constructed observing-room, "and we have neither the one nor the other at the Cape nor at Greenwich. If we are going to fight for two-tenths or three-tenths of a second, we must set to work *de novo* with better instruments, better housed, for the determination of constant error."

The Lunar Atmosphere.—Various are the methods that can be adopted for observing whether the moon has an atmosphere or not, but some of them, such as those that depend on solar eclipses, have been the least often attempted, since they are of an extremely delicate nature. In eclipses, whether partial or total, if the moon really had a moderately dense atmosphere, we should be able, by photographing the sun when partially covered by the moon, to note whether the delicate details on the solar surface in the region of the lunar limb had suffered any slight alterations in their forms. To note such variations it is needless to say that photography must be employed, and further that the photographs must be on a moderately large scale, for if indeed there be changes of form they will by no means be necessarily *very* apparent. For such observations as these no better scale could be used than that adopted by M. Janssen in those wonderful solar pictures that have done much to help us in extending our knowledge of the sun's surface. In fact M. Janssen, in *Comptes Rendus* for April 17 (No. 16) tells us that in order to try this method again several plates were exposed during the recent eclipse of the sun, but owing to the state of the sky the conditions were not very favourable, as these large photographs require a perfectly pure atmosphere. He mentions at the end of his note that he has already made some progress towards the solution of this question from the photographs that were taken at Marseilles during the partial eclipse of July, 1879.

GEOGRAPHICAL NOTES.

The Berlin Geographical Society has awarded the Humboldt medal, the highest honour it can bestow, to Dr. John Murray, editor of the *Challenger* reports, in recognition of the great advances in physical geography which are associated with his name.

The Paris Geographical Society has also awarded one of its gold medals to a foreigner, Dr. Fridjof Nansen. Other gold medals given by the Paris Society went to Captain Monteil, for his great journey to Lake Chad, M. Dybowski, for exploration on the Shari, and M. Lentheric for his monograph on the Rhone.

Mr. Guy Boothby has recently crossed Australia from north to south. He started from Normanton on the Gulf of Carpentaria in March, 1892, travelled leisurely on horseback or in a waggon to Bourke, and then descended the Darling in a boat, and later a river-steamer to Morgan, thence by rail to Adelaide. The journey occupied rather more than a year, and so far as appears little or no new country was traversed.

The May number of the *Scottish Geographical Magazine* contains a paper on the people of the Lake Nyasa region, by Mr. D. J. Rankin, in which he makes some serious charges against Mr. H. H. Johnston, the British Commissioner. Mr. Rankin considers the rule of the commissioner to be too severe, and finds fault with his knowledge of the native tribes and their claims to the land.

Mr. E. A. Floyer has a long paper in the *Geographical Journal* on the Eastern Desert of Egypt, illustrated by some very characteristic pictures and a new map, the result of his surveys. The expedition of which he was the leader was sent out by the Egyptian Government in 1891, and surveyed 23,000 square miles of mountainous desert. The region is crossed by a ridge of high ground in the higher peaks of which a few shepherds find a precarious pasture for their flocks, which feed on the comparatively thick growth of acacias. The water-supply is in the form of natural reservoirs of rain, in many cases contained in limestone cavities which keep the wells supplied.

The Columbus *fête* held in Paris on April 15, the 400th anniversary of the return of Columbus is reported at length in the current number of the *Revue de Géographie*, the main feature being an address by M. Ludovic Drapeyron, who presided. The novelty of such celebrations has passed, and it is difficult to see how the celebration of the fourth centenary of each episode of the life of Columbus after 1492 can be made serviceable to geography or of special interest to the public.

THE RECENT SOLAR ECLIPSE.

We have already printed a number of telegrams relating to observations of the solar eclipse of April 16 in various parts of the world, and now reproduce from the *Nottingham Daily Guardian* of May 9 an article on the work of the British party in West Africa. This article is contributed by a special correspondent of that journal, who writes from H.M.S. *Blonde*, Las Palmas, April 28. It contains the first detailed information which has appeared on the subject. The writer says:—

The expedition left Liverpool on March 18 by the British and African Company's steamer *Teneriffe*, the company having most generously contracted to convey them to the Gambia at greatly reduced rates. Bathurst, near the mouth of the Gambia, was reached on March 31, when the observers and their instruments were at once transferred to H.M.S. *Alecto*, which had been kindly placed at the disposal of the expedition by the Admiralty. The *Alecto*, being specially designed for service on the West African rivers, was eminently adapted to the purposes of the observers, and, indeed, without some such aid the expedition would have been impracticable. On the afternoon of April 2 the *Alecto* proceeded with the observers to the Salum River, which lies some distance to the north of the Gambia, and Fundium was reached on the following morning. The village, by the way, is called Goundiougne by the French. The chief occupation in this part of Africa is the raising of ground nuts for export. On arrival it was found that M. Deslandres and a small staff from the Paris Observatory had already been at Fundium a fortnight, and had got most of their instruments into position. A neighbouring site, kindly offered to the British party by the Administrator, was at once accepted as satisfying all requirements. It had the advantage of being partially enclosed, and was quite near to one of the wharves, so that the instruments could be put ashore without difficulty. The land around Fundium is very flat, and a perfectly clear horizon was therefore obtained. The site having been selected, plans for the arrangement of the various instruments were at once drawn, and the concrete bases were laid down, the necessary cement having been brought from Liverpool. Huts for the instruments, which had likewise been brought from England, and the instruments themselves were also erected with the least possible delay. In this preliminary work Lieutenant-Commander Lang and his staff, with the readiness characteristic of the British Navy, gave the party all needful assistance.

As eclipse work was new to all the observers, with the exception of Prof. Thorpe, who was in charge of the expedition, the instrumental equipment was such as not to overtax any of them. Prof. Thorpe, assisted by Mr. P. L. Gray, was in charge of a 6-inch equatorial telescope, belonging to Greenwich Observatory, with the necessary accessories for determining the intensity of the light at different points of the corona. The photometer used was of the form in which the amount of light from a glow lamp necessary to cause the disappearance of a grease spot on a piece of paper was determined by measuring the strength of the electric current which illuminates it. A number of such spots were so arranged in the photometer that the image of the corona formed by the telescope fell upon them, while on the other side they were illuminated by a glow lamp, the whole, of course, being inside a dark box. I myself, representing Prof. Norman Lockyer, had the management of a 6-inch photographic telescope, provided with a large prism in front of the object glass for the purpose of determining the chemical constitution of the corona and prominences. With this method of work a separate image of each position of the corona or prominences is obtained corresponding to each kind of light which it emits, and this gives the clue to its chemical character. A duplex telescope for photographing the surroundings of the eclipsed sun was in charge of Sergeant J. Kearney, R.E., who has had the advantage of a long and varied experience in photographic matters.

The instrument was provided with two object glasses of 4-inch aperture, the tube carrying them having a partition down the middle. The image formed by one of the lenses was received directly on the photographic plate, but in the other case it was magnified about three times by one of Mr. Dallmeyer's new telephotographic lenses. The dark slides carrying the photographic plates were ingeniously arranged so that by a single operation two plates were exposed. Lieutenant Hills, R.E., one of the volunteer observers was in charge of two spectroscopes of the ordinary form provided with slits. These were mounted on an equatorial stand, and were each provided with a 3-inch condensing lens. Here, again, photographic plates replaced the eye. A piece of apparatus for determining the total light of the corona was in the hands of Mr. Forbes, the other volunteer observer. Lieut.-Commander Lang undertook to make a drawing of the faint outlying parts of the corona by following the plan initiated by the American astronomer Newcombe in 1878. This consists in erecting a wooden disc in line with the eye and the eclipsed sun, and at such a distance that it appears to cover all the bright inner corona. The eclipse itself is thus eclipsed, and the observer has an opportunity of studying the more delicate parts of the corona, his eye being protected from the brighter light by the wooden disc.

The weather, fortunately, was magnificent during the whole tay of the observers at Fundium, and almost cloudless skies were experienced both day and night. By April 10 the instruments had all been carefully erected and adjusted by observations of the stars, and all was in readiness for the eclipse. Rehearsals of the operations which were to be gone through during the eclipse were now begun, and continued daily. It was arranged that the commencement of totality should be announced by pistol shot, Prof. Thorpe giving the signal to fire. Quartermaster Hallet was then to record in a loud voice the lapse of the 250 seconds of totality by reading the 15 seconds sandglass, which is so commonly used with the ship's log. Several rehearsals were gone through at dusk, when it was estimated that the light was about equal to that which might be expected during totality.

At last the day of the eclipse arrived, and everything was in complete order. The morning was a little more hazy than usual, but all felt confident of obtaining at least a moderate view of the eclipse. The observers themselves were at their posts soon after noon, and driving clocks and other details were attended to. At five minutes past one the moon was seen to have encroached on the south-western limb of the sun, and as it gradually passed over the disc the temperature of the air as gradually fell. At two o'clock the officers of the *Alecto*, who were kindly assisting the observers, also took their places. The light now waned very rapidly, and the breeze felt cold. In appearance the light of day at these stages very much resembled that which precedes an English thunderstorm. All the observers were now in perfect readiness for the pistol shot. "Five minutes" was announced by Prof. Thorpe, and I began my spectrum photographs, exposing six plates before totality. Amidst almost breathless silence the sound of the pistol shot was awaited. Eventually a similar pistol signal adopted in the French camp was clearly heard, and that moment the shadow of the moon went sweeping past. Prof. Thorpe's signal to fire, however, was not given until at least 10 seconds later. As the last trace of bright sunlight disappeared out flashed a magnificent corona of silvery light, together with numerous red and white prominences. The corona was very evenly distributed round the dark moon, that is to say, there were none of the great extensions along the Equator which were seen in 1878 and 1889. The light of the corona was very bright, and the lamps which had been provided for the use of the observers during totality were quite unnecessary—indeed, the sky light was so bright that no stars became visible at all, but Jupiter and Venus, which happened to be quite near the sun, shone out most distinctly. At Bathurst, however, the sky appears to have been clearer, and some of the brighter stars were also seen. The various observations were made and the photographs taken with no hitch whatever beyond the loss of about 10 seconds at the beginning of totality. This caused me to lose three exposures during totality, and reduced the number of Sergeant Kearney's photographs from 12 to 10. To err on the right side, Lieutenant Hills very fortunately closed his dark slides soon after "25 seconds" had been called by the quartermaster. In this case the slightest flash of sunlight would have been disastrous. Five minutes after totality was over I exposed my last plate, and the actual work of the expedition was at an end. What was more, all were confident of success.

Now, as to the results of the observations and photographs. Though it is much too early to attempt to state all that we may, except to learn from them, one point is clear. The general distribution of the corona is exactly what was expected, seeing that the sun is now in a very disturbed state. The sun spots, it is well known, have an eleven yearly period, and at the present time they are nearly at a maximum. This, in fact, made the recent eclipse one of the highest importance. It has been observed in previous eclipses that when the spots are at a minimum the corona is very much extended in the direction of the sun's equator, while, on the other hand, when the spots are at a maximum the corona is very much more evenly distributed. This supposed periodicity of the general form of the corona has received further confirmation by the recent observations. No unusual equatorial extension is shown on the excellent photographs taken by Sergeant Kearney, and none was observed by Lieut.-Commander Lang, who was specially looking for it. At Prof. Thorpe's suggestion Dr. Prout, the colonial surgeon at Bathurst, also erected a similar wooden disc, and his observations confirm those of Captain Lang. The prominences also follow the sun spots with regard to frequency, and, as already stated, a large number of them were seen. These are shown on Sergeant Kearney's photographs, and a complete record of the spectrum of each one is shown on the photographs taken by myself. The latter have the further advantage of showing the forms of the prominences as well as the spectra. Some of them chiefly show lines of hydrogen and calcium, while others again are almost crowded with lines of various metals. A complete record of the prominences has therefore been secured. With regard to the spectrum of the corona it seems doubtful at present whether our knowledge has made any great advance by the recent observations. The spectrum appears to have been very largely continuous, such as would be given by a mass of incandescent solid particles. One green line, which has previously been observed to be very prominent in the coronal spectrum, and the bright yellow line of the unknown substance, which is called helium, however, are shown in my photographs, and subsequent detailed examination may lead to the discovery of others. Lieut. Hill's photographs, which were specially exposed for the coronal spectrum, show a large proportion of continuous spectrum, and several lines which require further investigation. Much is to be hoped for, however, in another direction. The question of the constitution of the layers of the vapour which lie closest to the photosphere is one of the first importance to solar physicists. I had made arrangements to take two successive instantaneous spectrum photos as nearly as possible after the commencement of totality, but, as already stated, the opportunity was lost by reason of the lateness of the signal. The photos taken immediately after totality, however, promise to throw considerable light on the subject. Only two of these have been developed at present, and in addition to the ordinary spectrum of the uneclipsed part of the sun, they show large numbers of bright lines in the spectrum of those portions of the sun's atmosphere which were still left exposed by the moon. These, of course, also require a very detailed examination before any conclusion can be drawn. Of the thirty plates which I exposed only eleven have been developed so far, the facilities at Fundium not being very great. These were selected here and there from the whole series, and little doubt is entertained as to the good quality of the remaining plates. The photographic work was undertaken with the view of investigating the laws of variation in the brightness of the corona (1) according to the distance from the photosphere; (2) from one eclipse to another. Prof. Thorpe and Mr. Gray were successful in securing observations of the intensity of the light at sixteen different points of the corona, while Mr. Forbes made eleven measurements of the total light at as many different stages of the eclipse. All these observations were considered to be of a high degree of accuracy, but reduction to former standards and comparisons with measures at former eclipses have still to be made.

M. Deslandres' equipment consisted chiefly of spectroscopes of various forms, but in addition he was provided with instruments for photographing the eclipsed sun, one on a large and the other on a small scale. The haze somewhat interfered with his work, but he appears to have been fairly successful with such plates as were developed before the British expedition left.

The natives at Fundium were by no means alarmed during the eclipse, and there was fortunately no call for the guard of bluejackets, which Captain Lang had taken the precaution to place in the immediate neighbourhood of the instruments; indeed both here and at Bathurst the natives were sufficiently well informed to watch the progress of the eclipse through smoked glass. The cause of the eclipse seems to have been ascribed to the Almighty, and not in any way associated with the presence of the astronomers. The members of the expedition themselves had no opportunity of studying the effect of the eclipse upon the brute creation, but trustworthy observers in Bathurst report that the usual state of alarm prevailed amongst fowls, cats, and other animals. Immediately after the eclipse the huts were partly dismantled, and the observers and their instruments were photographed by Prof. Thorpe, exactly as during the operations, the astonished natives meanwhile gathering in large numbers. After a short rest, the work of dismounting and packing the instruments was begun, and before sunset considerable progress had been made. By the evening of April 17, all was packed and safely aboard the *Alecto*, and the only material remnants of the expedition were waste paper and a slab of cement, prepared and inscribed by Lieutenant Hills, with the words, "British Eclipse Expedition, April 16, 1893." It is impossible to speak too highly of the assistance rendered to the expedition by the officers and men of the *Alecto*. As already stated, Lieutenant-Commander Lang made independent observations, with the assistance of Lieutenant Colbeck. Prof. Thorpe and Mr. Gray were assisted by Mr. Pym, and myself by Lieutenant Shipton and Chief Artificer Milligan, Lieutenant Hills by Dr. Moore, Sergeant Kearney by Sergeant Williams, and Mr. Collick and Mr. Forbes, by Mr. Willoughby, the engineer, and Mr. Murphy, one of the artificers.

The expedition left Fundium on April 18, and arrived at Bathurst on April 19, where H.M.S. *Blonde* was waiting under orders to convey the party to Grand Canary. Without this convenient arrangement, the expedition could not have left Bathurst before May 3 or 4. The homeward journey to England will be completed by a passage in the first available steamer.

THE ORIENTATION OF GREEK TEMPLES.[1]

THIS investigation is supplementary to Mr. Lockyer's examination of the orientation of the Egyptian temples, in the course of which he has cited passages translated from hieroglyphics, showing most distinctly that there was a connection between the foundation of those temples and certain stars. He has also shown that the structure of the temples demonstrates that the light from these stars must have been admitted at their rising or setting along the axis of the temples through the doorways, and that in certain temples the doorways have been altered in such a way as to follow the amplitude of the star as it changed, owing to the precession of the Equinoxes, and that in some cases a new temple had been founded alongside of an older one for the same purpose.

Although there does not seem to be any historical or epigraphical record of such a nature in Greece, the architectural evidence is not wanting. On the Acropolis of Athens there are two temples, both dedicated to Minerva, lying within a few yards of one another, both apparently oriented to the Pleiades, the older temple to an earlier position of the star group, and the other to a later one. At Rhamnus there are two temples almost touching one another, both following (and with accordant dates) the shifting places of Spica. In a temple at Ægina a doorway placed excentrically in the west wall of the cella was adapted for the observation of a setting star.

A clue is given for finding out the dates of the foundations of temples oriented to stars by means of the changes produced upon them by the precession of the Equinoxes; a movement which induces a divergence between the latitudes and longitudes of stars, and their places reckoned in declination and right ascension; so that after the lapse of 200 or 300 years a star which rose or set in the direction of the axis of a temple would have passed to a different amplitude, so as to be no more available for observation, as before, from the adytum.

In the earlier ages of Greek civilisation the only accurate measure of time by night was obtained by the rising or setting of stars, and these were more particularly observed when heliacal, or as nearly as possible to sunrise. For the purpose of temple worship, which was carried on almost exclusively at sunrise, the priests would naturally be very much dependent for their preparations on the heliacal stars as time warners.

The orientation of temples may be divided into two classes, solar and stellar. In the former the orientation lies within the solstitial limits; in the latter it exceeds them. In Greece there are comparatively few of the latter class.

In the lists of temples which follow, all the orientations were obtained from azimuths taken with a theodolite, either from the Sun or from the planet Venus. In almost every case two or more sights were observed, and occasionally also the performance of the instrument was tested by stars at night. The heights subtended by the visible horizon opposite to the axes of the temples were also observed.

The first list comprises twenty-seven intra-solstitial temples:

7	examples from	Athens.	1	example from	Sunium.
3	,,	Olympia.	1	,,	Corinth.
2	,,	Epidaurus.	1	,,	Bassæ.
2	,,	Rhamnus.	1	,,	Ephesus.
2	,,	Ægina.	1	,,	Platæa.
1	,,	Tegea.	1	,,	Lycosura.
1	,,	Nemea.	1	,,	Megalopolis.
1	,,	Corfu.	1	,,	Argos.

For all these the resulting solar and stellar elements are given, with the approximate dates of foundation, similarly to the following specimen, namely, that of the Temple of Jupiter at Olympia.

Olympia, lat. 37° 38′ *N.*

Temple of Jupiter	Orientation angle.		Stellar elements.	Solar elements.	Name of star.
	262° 37′ 46″	Amplitude, star or sun	8° 38′ 0″ N.	7° 22′ 14″ N.	
		Corresponding altitude	3 0 0 E.	1 42 0 E.	
		Declination	+8 40 0	+6 52 22	
		Hour angles	$6^h\ 11^m\ 37^s$	$7^h\ 34^m\ 52^s$	
		Depression of sun	...	14° 12′ 0″	
		Right ascension	$23^h\ 40^m\ 0^s$	$1^h\ 3^m\ 5^s$	
		Approximate date	B.C. 740	Apr. 6.	

This example has been selected from the rest of the list because this temple has been chosen for the purpose of showing the method of procedure in working out the elements from the observations, those, namely, of the orientation angle, and of the height of the visible horizon.

A few general remarks, however, seem required respecting the Sun's and star's altitude, and the Sun's depression when the star is to be observed.

For a star to be seen heliacally, it is necessary that the Sun should be just sufficiently below the horizon for the star to be recognised. According to Biot, Ptolemy, speaking of Egypt, has recorded this to be about 11°. But where, as generally in Greece, there are mountains screening the glow which at such times skirts the true horizon, it seems fair at any rate for a first magnitude star to consider 10° as sufficient. I have myself seen Rigel in the same direction as the Sun when elevated 2° 40′ above the sea horizon, the Sun being less than 10° below. Obviously an observer looking from a dark chamber in a well known direction would be more favourably situated.

It is proper to allow about 3° of altitude for a star to be seen above low clouds and the hazy glow which skirts the horizon. The Sun's light, however,, seems to be very effective at a lower altitude, and when he appears over a mountain of 2° or 3° altitude the angle may properly be reduced by 20′ or 25′, partly for refraction, and partly because a small segment only of the disc is sufficient for illumination.

The method I have pursued in working out the example of the Temple of Jupiter at Olympia is as follows.

The orientation angle, measured from the south point round by way of west and north, is 262° 37′ 46″, which is equivalent to an amplitude of + 7° 22′ 14″. The eastern mountain subtends an angle of 2° 4′. For reasons above given, the solar altitude

[1] Abstract of a paper (read before the Royal Society on April 27), "On the Results of an Examination of the Orientation of a number of Greek Temples, with a view to connect these Angles with the Amplitudes of certain Stars at the time these Temples were founded, and an endeavour to derive therefrom the Dates of their Foundation by consideration of the changes produced upon the Right Ascension and Declination of the Stars arising from the Precession of the Equinoxes." By F. C. Penrose, F.R.A.S. Communicated by Prof. J. Norman Lockyer, F.R.S.

may be taken as $1° 42'$, but that of the star, $3°$. Combining these values with the latitude, viz., $37° 38'$, and using the formula

$$\sin \delta = \cos \text{zen. dist.} \times \cos \text{colat} + \sin \text{zen. dist.} \times \sin \text{colat} \times \sin \text{ampl.},$$

we obtain for the star a declination of $+7° 40'$, and for that of the Sun $+6° 52' 22''$. This latter, with the ecliptic obliquity of about 800 years B.C., determines the Sun's right ascension to have been 1h. 3m. 15s.

The next step is to inquire if there be any bright star or star group which, at a date consistent with archæological possibility, would have had a declination near to the above-named place, and would also have been heliacal.

Such a star would have required about 6h. 8m. to pass from $3°$ altitude to the meridian, and it would have required to have been about $1\frac{1}{2}$h. in advance of the Sun to allow it to be seen. The approximate R.A. of such star would therefore be about 23h. 40m., and its declination, as already stated, must be about $7° 40'$ N.

For trials I have used a stereographic projection of the sphere taken on the pole of the ecliptic, but showing also R.A. hours and parallels of declination. Any place on this projection may be chosen and marked on a superimposed sheet of tracing paper, and then if the tracing paper is turned round upon the pole of the ecliptic as a centre, so that the straight line drawn upon it, which in the first instance joined the two poles marked on the projection is carried round to an angle equal to the amount of precessional movement under consideration, if there be a suitable star marked on the projection the point selected for trial will pass over it or near it, and after the star has been thus roughly pointed out the more exact calculations may be proceeded with. By this process in the case before us the tracing-paper mark coincided almost exactly with the place of α Arietis, and for this star the particulars were carefully computed which have been given in the list of elements.

It should be noticed that there are in every case of intra-solstitial temples four possible solutions of this step. The Sun's amplitude may be due either to the vernal or the autumnal place, and the star might have been heliacal either at its rising or setting. In every instance all these four alternatives have been tried by the preliminary search method, and in every case in temples of old foundation an heliacal star has resulted from one or other of the trials, but never more than one.

The star which has been found as above for the Temple of Jupiter is no other than the brightest star of the first sign of the Zodiac, and therefore peculiarly suited to that god. The same star is connected with the early temple of Jupiter Olympius at Athens.

In intra-solstitial temples, by the nature of the case, the stars are almost entirely confined to the Zodiacal constellations, and consequently suitable stars are very much limited in number.

Another very great limitation arises from the consideration that, to have been of any service as a time warner, the star must have been heliacal, and when these two limitations are taken into account it becomes improbable to the greatest degree that there should always have been a suitable star unless it had been so arranged by the builders of the temple.

In about two-thirds of the cases which I have investigated the dates deduced from the orientations are clearly earlier than the architectural remains now visible above the ground. This is explained by the temples having been rebuilt upon old foundations, as may be seen in several cases which have been excavated, of which the archaic Temple of Minerva on the Acropolis of Athens and the Temple of Jupiter Olympius on a lower site are instances. There are temples also of a middle epoch, such as the examples at Corinth, Ægina, and the later temples at Argos and at Olympia (the Metroum at the last named), of which the orientation dates are quite consistent with what may be gathered from other sources.

Besides the list of intra-solstitial temples already given I have particulars of five for which I have been unable to find an heliacal star. They are all known to be of recent foundation, when other methods of measuring time had been discovered. The solar axial coincidences were no doubt in all these cases connected with the great festivals of these temples. It was clearly the case in two of them.

At the Theseum at Athens the date was either October 10 or March 2. The *Thesea* festival is reckoned to have been on October 8 or 9. For the later Erechtheum the day would have been April 8 or September 3. The great festival of this temple is put down for September 3.

Leaving the solar temples, we find that the star which was observed at the great Temple of Ceres must have been Sirius, not used, however, heliacally—although this temple is not extra solstitial—but for its own refulgence at midnight. The date so determined is quite consistent with the probable time of the foundation of the Eleusinian Mysteries and the time of year when at its rising it would have crossed the axis at midnight agrees exactly with that of the celebration of the Great Mysteries.

It is reasonable to suppose that when, as in the case of Sirius at Eleusis, brilliant stars were observed at night, the effect was enhanced by the priests by means of polished surfaces.

Herodotus, speaking of a temple at Tyre (B. II, 44), says:—

"*Καὶ ἐν αὐτῷ ἦσαν στῆλαι δύο, ἡ μὲν χρυσοῦ ἀπέφθου, ἡ δὲ σμαράγδου λίθου, λάμποντος τὰς νύκτας μέγαθος.*"

(Two shafts, one of pure gold, the other of emerald, which shone remarkably at night.)

Of a list of seven extra-solstitial temples which are named, five are more particularly noticed, viz. :—

A temple at Mycenæ and one near Thebes, which are built nearly north and south, but which probably, as was the case at Bassæ, had eastern doorways. The star, α Arietis, which suits the first, seems to point out the dedication of this temple to Jupiter. The other is very remarkable, and connects the Bœotian Thebes with the great Egyptian city; the star was γ Draconis. Thebes was called the City of the Dragon, and tradition records that Cadmus introduced both Phœnician and Egyptian worship. Three of the temples lay more nearly at an angle bisecting the cardinal points; these are Diana Propylæa at Eleusis, a small temple (not yet named) lately discovered at Athens, and the Temple of Venus at Ancona, recovered by means of the walls of a church built upon its traditional site. In these temples the star observed at the first seems to have been Capella, the time of the year when it shone axially at midnight agreeing with that of the celebration of the Little Mysteries, and in the other two the star was Arcturus.

EXPLORATIONS IN THE KARAKORAM.

MR. W. M. CONWAY gave an account of his recent exploring expedition in the Karakoram mountains at the last meeting of the Royal Geographical Society. The paper was illustrated by lantern slides, and a series of paintings by Mr. McCormick, who accompanied the expedition, was also exhibited. Mr. Conway said:—We left Srinagar on April 13, 1892, and came to Gilgit. Arrived at Gilgit we found the condition of the mountains, from a climber's point of view, too backward for our purposes. We therefore spent a month in mapping and exploring the fine Bagrot Valley, which slopes southwards from Rakipushi and its immediate neighbours along the main ridge. We hoped to be able to force a passage over this ridge into Nagyr; but the persistent bad weather baulked our efforts when they were on the point of succeeding. When the traveller has emerged from the inhospitable defiles which sunder the valley of Hunza Nagyr from Gilgit, and has climbed the vast ancient moraines near Tashot, which form the final rampart of the fertile basin (fertile, of course, only by reason of artificial irrigation of admirable complexity and completeness), he stands surrounded by an astonishing view. The bottom of the valley is, as usual, deeply filled by *débris*, whose surface is covered by terraced fields, faced with cyclopean masonry, and rich with growing crops and countless fruit trees. The mountains fling themselves aloft on either hand, with astounding precipitancy, as it were into the uttermost heights of heaven; so steeply, in fact, that a spring avalanche falling from the summit of Rakipushi on the south must almost reach the bottom of the valley. Rakipushi is 25,500 feet high; the Hunza peak is about 24,000 feet high. Their summits are separated by a distance of 19 miles. Both mountains are visible from base to summit at one and the same time from the level floor of the valley between them, which is not more than 7000 feet above the sea. No mountain view that I saw in the Karakorams surpasses this for grim wonder of colossal scale, combined with savage grandeur of form and contrast of smiling foreground.

Having been beaten back on June 24 from an attempt to reach the Bagrot Pass from the north, we returned to Nagyr, and started inwards towards the wholly-unknown region. We left Nagyr behind on June 27, and in a mile or two came to the foot of the Hopar Glacier. This glacier was once joined by the Hispar Glacier, and their united moraines were deposited at Nagyr, the town being actually built upon their crest. Now the foot of the Hispar Glacier has retreated some twenty miles into the mountains. The Hopar Glacier is greatly shrunken in width, and in its shrinkage it has left a fine, almost level area, beside its left bank, which is covered by the fields of Hopar.

We were delighted to find an enormous and almost unsuspected series of glacier basins above Barpu. In order to get some idea of them we spent a day mounting to the crest of the ridge north of our camp, which divides Barpu from the Hispar Valley. The view was of peculiar interest to us, for we looked for the first time into the Hispar Valley and beheld the long avenue of peaks that lined the way up the Hispar Glacier towards the unknown snowy regions through which lay our intended route into Baltistan. We reached the summit of the Hispar Pass on July 18, and Askole on the 26th, our slow progress being caused by the exigencies of the survey in weather that was oftener bad than fair.

We left Askole on July 31 and returned to it again on September 5, the intervening time having been spent over our expedition up the Baltoro Glacier and the ascent of Crystal and Pioneer Peaks. On September 10 we embarked on a skin raft, which carried us down the Shigar River to the Indus. We landed, and in half an hour reached the scattered villages of Skardo, capital of Baltistan. Of our journey from Skardo to Leh to verify our instruments, and from Leh back to Srinagar, it is unnecessary to speak. We reached Abbottabad on October 28, exactly seven months from the day on which we left it.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—During this term Prof. Clifton is lecturing on the optical properties of crystals, and other lectures and practical instruction are given by Mr. Walker and Mr. White at the Museum, by Mr. Baynes at Christchurch, by Sir J. Conroy at Balliol, and Mr. F. J. Smith at Trinity. In chemistry, Mr. Fisher and Mr. Watts are lecturing on inorganic and organic chemistry respectively, and Messrs. V. H. Veley and J. E. Marsh are demonstrators at the Museum. Mr. Vernon Harcourt is lecturing on inorganic chemistry at Christchurch, and Mr. D. H. Nagel at Trinity.

The professor of geology announces a course of lectures on economic geology and geological excursions. Prof. Ray Lankester is giving two courses, on embryology, and on the protozoa, rotifera, and urochorda; and supplementary lectures are given by Dr. Benham, Mr. J. Barclay Thompson, Mr. Bourne, and Mr. Minchin.

Prof. Burdon Sanderson is lecturing on the central nervous system, and has the assistance of Dr. Haldane and Mr. Pembury.

Prof. Vines is lecturing on outlines of classification, and has appointed Mr. P. Groom, of Cambridge, as demonstrator.

At the end of last term a sum of £3500 was voted by Convocation towards the renewal of a portion of the buildings and hothouses in the Botanic Garden. Prof. Vines made a full report on the condition of the houses at the end of last year, showing that all were old, of faulty construction, and so dilapidated as to entail a heavy annual expenditure for repairs. At the same meeting of Convocation a sum of £1000 was placed to the credit of the delegates of the University Museum, to be employed at their discretion for the maintenance and improvement of the collections in the Museum.

At a meeting of the Ashmolean Society on Monday, May 1, under the presidency of Mr. E. B. Poulton, Prof. A. W. Rücker, F.R.S., gave an interesting lecture on the electrical conductivity of thin films, which was largely attended.

On the 16th inst. Lord Kelvin will give the annual Boyle lecture to the Junior Scientific Club, and on the 18th the Romanes lecture will be given in the Sheldonian theatre by the Right Hon. T. H. Huxley.

Cambridge.—The term for which Mr. J. Y. Buchanan, F.R.S., was appointed to the University Lectureship in Geography expires at the end of the present term. The Committee of Selection for the appointment of a Lecturer to hold office for the next five years, will meet at Gonville and Caius Lodge on May 31. The stipend of the Lecturer is £200 a year, and he is required to deliver courses of Lectures in Geography during two terms at least, and to give informal instruction and assistance to students attending his lectures, and to promote the study of his subject in the University. The retiring lecturer is re-eligible. Candidates are to send their names and testimonials to the Master of Gonville and Caius College, on or before May 27.

The first Arnold Gerstenberg Studentship, of the value of £90 a year for two years, will be competed for in May, 1894, by men or women who have obtained honours in either part of the Natural Science Tripos, and whose first term of residence was not earlier than the Easter term 1888. The subjects of examination are Logic and Psychology, and the successful candidate must undertake to pursue a course of philosophical study.

Applications for permission to occupy the University's tables at the Zoological stations of Naples and Plymouth are invited; they should be addressed to Prof. Newton, and reach him on or before May 25.

The names of Prof. John Couch Adams, and of William, seventh Duke of Devonshire, have been inserted in the list of Benefactors of the University, recited at the annual Commemoration Service.

The plans for the Sedgwick Memorial Museum of Geology, prepared by Mr. T. G. Jackson, A.R.A., were approved by a large majority, in the Senate on Thursday last. The work of construction cannot however be begun until the finances of the University, which this year show a deficit of some £4000, are in a more satisfactory state. A proposal to raise funds, by increasing the capitation-fee paid by undergraduates from 17s. to 40s. a year, is now before the Senate.

Alfred Eichholz, B.A., first class in both parts of the Natural Science Tripos 1891–92, with distinction in physiology, has been elected to a Fellowship at Emmanuel College. Mr. Eichholz has already published papers of interest on physiological and anatomical subjects, and his election reflects great credit on his college.

SCIENTIFIC SERIAL.

Bulletin of the New York Mathematical Society, vol. ii. nos. 5, 6 (New York, 1893).—The earlier number opens with an account of the theory of substitutions (pp. 83–106), by Prof. Oskar Bolza. This is a warmly appreciative notice of Dr. F. N. Cole's translation of Netto's "Theory of Substitutions and its Applications to Algebra," to which attention has recently been drawn in our columns (see Nature, pp. 338, 339).—Dr. M. Bôcher in a bit of mathematical history (pp. 107–109) calls attention to a remarkable memoir by Euler ("De motu Vibratorio Tympanorum," 1764).—No. 6 contains a paper read before the New York Mathematical Society by Dr. T. Craig on some of the developments in the theory of ordinary differential equations (pp. 119–134). This is likely to be useful to students. Another paper read before the same Society is one entitled "On a General Formula for the Expansion of Functions in Series," by Prof. Echols (pp. 135–144), which is intended to be a brief exposition of a general theorem which forms the basis of a series of papers on certain determinant forms and their applications.—A short note follows by Dr. E. McClintock on the early history of the non-euclidian geometry (pp. 144–147), in continuation and part correction of his previous note in No. 2 of this volume. It discusses the claim to priority, brought forward recently by Prof. Beltrami, of Saccheri (1733) in his "Euclides ab omni nævo Vindicatus" as against Lobatschewsky.—"Notes" and "new publications" complete each number.

SOCIETIES AND ACADEMIES.

London.

Royal Society, February 16.—"On a Portable Ophthalmometer." By Dr. Thomas Reid, Glasgow. Communicated by Lord Kelvin, P.R.S.

The object of this instrument is to measure the curvature of the central area of the cornea, the polar or optical zone, and as this polar zone is the part of the cornea utilised for distinct vision, the instrument furnishes all the data practically requisite for the diagnosis and measurement of corneal astigmatism. Its use may be extended to the measurement of convex and concave reflecting surfaces within the limits of this instrument, *i.e.* from 6 to 10 mms. of radius.

The theory of its construction is based on a particular application of the following well-known optical law:—that when two centred optical systems are so combined that their principal foci coincide, the ratio of the size of the object to the size of the image formed by the combined systems is equal to the ratio of the principal foci of the two optical systems adjacent respectively to object and image. The two optical systems in this case are a convex lens and the cornea as a reflecting surface, the object being in the principal focus of the convex lens.

The instrument is composed of the following parts: an aplanatic lens of 26 mms. focus, a rectangular prism neutralised in the visual axis by a smaller prism, one side of the rectangular prism being adjacent to the lens and an iris diaphragm being opposite to the other side in the principal focus of the lens. Behind the prism is a telescope with a double image prism fixed in front of the object glass of the telescope, which has precisely the same focus as that of the aplanatic lens. Cross wires at its principal focus are viewed by a Ramsden eye-piece.

Before using the instrument it is essential that the cross wires should be distinctly seen at the punctum remotum of the observer. The adjusted instrument is held in the observer's left hand, which rests on the forehead of the patient, the diaphragm being directed to a luminous source to the right of the observer. When the observed eye is directed to the central or fixation point of the instrument, the image of the diaphragm in the cornea can only be distinctly seen, when the principal focus of the lens coincides with the principal focus of the cornea, the point of coincidence of the principal foci being found by moving the instrument to and fro. The image of the diaphragm by means of the double image prism appears as two images in the centre of the field, when the visual line of the observer's eye is perpendicular to the surface of the cornea, through which it passes. If these images are not seen in the centre, their position indicates the direction of the angle *a*. The size of the corneal image being constant (2 mms.) the images are brought into exact contact by suitable variations of the iris diaphragm. By using a circular object, the circular, elliptical or irregular form of the image reveals at once the condition of the surface. When the images are elliptical, the minor axes of the two images are to be brought into the same straight line by a rotation of the telescope, and similarly with the major axes.

Equal differences in the size of the diaphragm correspond to equal differences in dioptric power, each millimetre of difference in diameter corresponding to three dioptres. The amount of astigmatism in dioptres can thus be read off on a graduated scale fixed to the instrument.

This instrument reads certainly to within half a dioptre, which between 7 and 8 mms. of radius of curvature is equivalent to $\cdot 08\dot{8}$ mms. of difference of radius.

April 20.—"The Potential of an Anchor Ring," by F. W. Dyson, Fellow of Trinity College, Cambridge, Isaac Newton student in the University of Cambridge. Communicated by Prof. J. J. Thomson, F.R.S.

This paper is a continuation of some researches on rings published in the Phil. Trans. 1893. A system of solutions of Laplace's equation applicable to space *inside* an anchor ring is found. By means of these and the value of the potential at external points found in the previous paper, the potential of a ring at internal points is found. The stability of the annular form of rotating gravitating fluid is discussed; the ring form is shown to be stable for fluted and twisted disturbances, but unstable for long beaded ones. The potential of a ring of gravitating matter whose cross section is elliptic is obtained. Applying the result to Saturn's system, it is shown that for his ring to be continuous fluid its density would have to be 100 times that of the planet. The steady motion of a single vortex-ring of finite cross section in an infinite fluid is discussed, and also the motion of a number of vortex rings on the same axis. Numerical calculations are entered into for the particular cases of a vortex ring followed by another of equal strength, a vortex ring approaching an infinite plane, and one passing directly over a spherical obstacle.

Physical Society, April 28.—Prof. W. E. Ayrton, F.R.S., Past-President, in the chair.—Adjourned discussion on the viscosity of liquids, by Prof. J. Perry, J. Graham, and L. W. Heath. Prof. Perry read a communication he had received from Prof. Maurice Fitzgerald on the subject, in which the latter discusses the corrections necessary for reducing the results obtained by circular motion to the corresponding motion in plane layers. He shows that in addition to the circular motion, the effect is complicated by radial flow due to "centrifugal head," which causes the liquid to pass outwards near the bottom of the trough and inwards across the edge of the suspended cylinder, with continuations along the sides of the trough and cylinder. Taking this motion into account the formula $v = Ar^{1+\frac{c}{\mu}} + \frac{B}{r}$ is deduced, where v is the velocity, μ the viscosity, A and B arbitrary constants, and c a constant depending on the radial flow. When $c = 0$ the formula reduces to equation (5) of the paper, whilst if $c = -2\mu$ it becomes $v = \frac{C}{r}$. The subject of critical velocities in non-turbulent motion is referred to, and some probable effects of the anomalous variations of density and viscosity of sperm oil noticed by the authors of the paper are pointed out. Prof. Perry, in further reply to Prof. Osborne Reynolds' comments, said he understood Prof. Reynolds to have proved that friction was proportional to velocity when the motion was steady. Experiments he (Prof. Perry) had made with discs of iron and glass in revolving mercury seemed to show that this was not the case. On replacing the mercury by sperm oil he found that up to a certain speed friction was strictly proportional to velocity, whilst above that speed friction varied as $v^{1\cdot 25}$. Coloured streaks in the liquid remained unbroken even at the highest speeds. He therefore concluded that continuity of the streaks was not necessarily accompanied by a linear law of friction.—Mr. E. C. Rimington read a paper on luminous discharges in electrodeless vacuum tubes. The luminous rings produced in exhausted bulbs and tubes by discharging Leyden jars through coils surrounding them, had, he said, been attributed by Mr. Tesla (*Elec. Eng. of New York*, July 1, 1891) to the electrostatic action of the surrounding wire rather than to the rapidly varying magnetic induction through the rarefied gas. The present paper describes several experiments bearing on this point which lead the author to conclude that varying magnetic induction is the chief cause of the luminous rings. They also show that a superposed electrostatic field greatly assists the production of the luminosity. Most of the experiments described were performed before the meeting, some of the effects being particularly brilliant. In one experiment an exhausted bulb was placed within a coil connecting the outside coatings of two Leyden jars and placed between two metal plates, which could be connected at will with the outside of either jar. The spark gap between the inner coatings was then arranged so that no luminosity was seen in the bulb. On connecting one or both the metal plates with the jars in such a way as to increase the electrostatic field through the bulb, bright rings immediately appeared. An electrostatic field produced by a small induction coil connected to a piece of tin-foil on the bulb caused the rings to form at irregular intervals when the discharge of the jars and coil happened to be properly timed. In another experiment two loops of wire in series were used, and when put on the bulb in such a way as to produce a large magnetic effect but small electrostatic field, bright rings appeared, but if the magnetic effects of the coils opposed each other, whilst the electrostatic field was increased, no rings were seen. The subject is treated mathematically at some length in the paper, the times at which the maximum values of the current, the potential difference between the outside of the jars and the rate of change of current occur, as well as the values of their successive maxima being determined. The influence of size of jars is next considered, and the time-integral of rate of change of current on which the effect on the eye depends, expressed as a geometrical series. Taking an approximation the author shows that the time-integral is roughly proportional to the fourth root of the capacity. Large jars are therefore theoretically only slightly better than small ones, and this agrees with observation. On the subject of apparently unclosed discharges, such as are seen when discharges pass through a coarse spiral wound on an exhausted tube, the author said he had observed that the discharges were really closed, but the return part much diffused and of feeble intensity. Experiments were exhibited showing that under some circumstances an exhausted bulb acted like a closed metallic circuit, whilst under other conditions dissimilar effects were produced. Another experiment was shown in which a faint luminous ring, produced by a single turn of insulated wire round a bulb, was apparently repelled on touching the wire with the finger. The author also showed that fan-shaped luminosities could be produced by rotating an exhausted tube in the electrostatic field produced by a charged ebonite or glass rod. Dr. Sumpner, speaking of the apparently unclosed discharges, pointed out that they might be closed through the wire forming the primary circuit, in the same way as the coil of a transformer might be arranged to act partly as primary and partly as secondary. Mr. A. P. Trotter, after referring to Dr. Bottomley's researches, said it was important in discussing such experiments to distinguish between electrostatic and electromagnetic effects. In Mr. Campbell Swinton's experiments the luminosity always appeared to get as far away from the wire as possible and to be at right angles to it, whereas in Mr. Rimington's the luminous portions were close to the wire. With a view to puzzling the discharge in Mr. Swinton's tubes he had made a right-angled bend in the spiral surrounding the tube, the result of which was to make the luminosity discontinuous, one end of the break being bifurcated. In all Mr. Swinton's experiments brush discharges surrounded the wire. Prof. S. P. Thompson thought an electrostatic field would aid a discharge even if its direction was not the same as the E.M.F. due to varying magnetic induction. Planté had found that vacuum tubes through which 800 cells were insufficient to produce a discharge, immediately allowed a discharge to pass when a rubbed ebonite rod was brought within about 10 feet distance. This effect was found to be independent of the direction of the disturbing field. Analogous effects had also been observed by Prof. Schuster, and described in his Bakerian lecture. Mr. E. W. Smith regarded the stresses set up in the medium as cumulative, a very slight cause acting on a substance already strained nearly to breaking point, being sufficient to cause breakdown. Mr. Blakesley inquired if the effects were the same if the induction coil, used in one of the experiments, was replaced by an electric machine, and whether the direction of the field so produced influenced the result. Mr. W. R. Pidgeon said closed circuits were necessary, and he had found it very difficult to produce discharges in tubes unless the ends of the primary wire were brought together. In his reply Mr. Rimington said each turn of the luminous spiral formed a complete circuit of itself. The phenomena observed by Mr. Campbell Swinton were quite different to those he had shown, and due to different causes. Mr. Swinton's spirals were reversed, and were due to phosphorescence of the glass.

Zoological Society, April 18.—Sir W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's menagerie during the month of March, and called special attention to three White-tailed Gnus (*Connochætes gnu*) from the Transvaal (a male and two females), obtained by purchase March 7, and to three Springboks (*Gazella euchore*) from South Africa, deposited by H.R.H. the Prince of Wales.—Mr. Sclater exhibited and made remarks on a specimen of a curious variety of the Pig-tailed Monkey (*Macacus nemestrinus*) from the Baram River, Sarawak, lately living in the Society's menagerie.—Mr. Sclater read a communication received from General Sir Lothian Nicholson, Governor of Gibraltar, respecting the Barbary Apes (*Macacus inuus*) living on the Rock of Gibraltar, which were stated to have increased of late years, and were now supposed to be nearly sixty in number.—Mr. W. L. Sclater made some remarks on the principal animals noted in the Zoological Gardens of Antwerp and Amsterdam, which he had lately visited.—A communication was read from Mr. A. E. Shipley containing an account of the anatomy and histology of two Gephyrean worms of the genus *Sipunculus* from Zanzibar, together with a few observations on Sipunculids in general.—Mr. Oldfield Thomas gave an account of a small collection of Mammals obtained in Central Peru by Mr. J. Kalinowski. Amongst several species represented in this collection, either new or of such interest as to deserve a record was especially noted a new form of Rodents of the family, Muridæ, proposed to be called *Ichthyomys stolzmanni*.—Mr. H. J. Elwes read a communication from Mr. W. Warren describing a large number of new species and new genera of Moths of the family Geometridæ in Mr. Elwes's collection, from Sikkim and other districts of India. Notes on the localities and on other points were added by Mr. Elwes.

Geological Society, April 26.—W. H. Hudleston, F.R.S., President, in the Chair.—The following communications were read:—The origin of the crystalline schists of the Malvern Hills, by Dr. Charles Callaway. This paper was the third of a series of three. In the first of these, published in the *Quarterly Journal* in 1887, the author contended that many of the gneisses and schists of Malvern were formed out of igneous rocks. In the second, which appeared in the Journal in 1889, he discussed the origin of secondary minerals at shear-zones in the Malvern rocks, and arrived at the conclusion that all the mica and much of the felspar, to say nothing of quartz and other minerals, were of secondary origin. In the present paper the author first pointed out that some of the most important mineral changes described in his second communication—such, for example, as the conversion of chlorite into biotite—had since been confirmed by independent investigators. He held that, as a whole, the gneisses and schists of Malvern had been formed by the crushing and shearing of consolidated igneous rocks; but he did not deny the possibility that here and there the foliated structure might have been produced in a fused mass. In the first stage of metamorphism the diorite or granite was crushed and decomposed. This slightly compressed rock could be traced step by step into a typical gneiss or schist. The signs of pressure progressively increased, and the mineral and chemical changes became proportionately greater. Reconstruction set in. The process of metamorphism did not always follow the same lines. Felspar was sometimes crushed into seams of fragments, and these, by partial re-fusion and pressure, were converted into gneissose lenticles of quartz and felspar. Intervening chlorite was changed to biotite, or even to muscovite or sericite. Thus a typical gneiss, consisting of quartz-felspar lenticles in a felt-work of mica, was formed out of a diorite. Sometimes the felspar was reconstituted without becoming fragmental; and it was then deposited on, or it included, idiomorphic mica. Or a soda-lime felspar might, by a process of corrosion, be converted into quartz, or a soda-felspar, or both. In an early stage of metamorphism, the rock was often dirty and rotten through the abundance of chlorite and disseminated iron oxide. The former being changed to mica, and the latter being either absorbed in the production of biotite, or reconstituted in a crystalline form, a sound clear gneiss was the result. In the completed product, the signs of crushing and shearing were often entirely wanting. Even strain-shadows were rare in it. The metamorphism, however, was demonstrated in numerous localities by tracing the gradations inch by inch, and by the subsequent study of large numbers of microscopic slides, in which the transition was still more clearly seen than in the field. The classification of the Malvern schists originally proposed was somewhat enlarged, the injection-schists being subdivided into —(1) Schists of primary injection, in which one rock was injected into another, and (2) Schists of secondary injection, formed by the infiltration of secondary minerals along shear-planes. One of the most important of the chemical changes produced in the conversion of a diorite into an acidic schist was the elimination of magnesia. This was proved by analysis. The recent researches of Mr. Alexander Johnstone had shown that even in the laboratory, and at the ordinary temperatures, carbonated waters were able to remove magnesia from certain of its combinations with silica. The reading of this paper was followed by a discussion, in which the President, Prof. Bonney, Mr. Harker, Mr. Rutley, Prof. Hull, and the author took part.—Supplementary notes on the metamorphic rocks around the Shap Granite by Alfred Harker, and J. E. Marr, F.R.S. This paper contains some additions and corrections to the work submitted to the Society by the authors on a previous occasion (see *Quart. Journ. Geol. Soc.* vol. xlvii. p. 266). In the present communication special attention is paid to the alteration of a group of basic volcanic rocks by the granite. Some remarks were made on this paper by the President, Mr. Rutley, Mr. Teall. Mr. Harker and Mr. Marr replied.

Linnean Society, May 4.—Prof. Stewart, President, in the chair.—Dr. R. B. Sharpe exhibited some new and rare birds from Borneo, and made remarks upon the singular distribution of the genera to which they belonged. On behalf of Miss E. M. Sharpe he also exhibited both sexes of the larvæ and cocoons of a rare silkworm moth, *Gonometa fascia* from Lagos. Prof. J. B. Farmer exhibited under the microscope some preparations showing attraction spheres in Hepatic spores, and gave the result of his recent researches on the subject.—Mr. Thomas Christy exhibited some curious variations in foliage in plants of a *Sterculia* from Brazil, reared from the same pod, and showed also a specimen of *Erythroxylon Coca* in fruit.—Mr. W. B. Hemsley showed two British plants which were interesting on account of the localities, namely *Empetrum nigrum* from Dorset (where Mr. C. B. Clarke had seen it growing on Poole Harbour Spit though it had not been included hitherto in the county flora), and *Scilla nutans* with prolonged bracts, usually regarded as an introduced garden form, which had been found growing apparently wild in a wood near Ashford, Kent. —Mr. Alfred Sanders then read a paper on the nervous system of *Myxine glutinosa*, a fish allied to the Lampreys.

DUBLIN.

Royal Dublin Society, April 19.—Prof. A. A. Rambaut, Astronomer Royal for Ireland, in the chair.—Dr. J. Joly, F.R.S., described a method of detecting the existence of variable stars by continuous photometric observations from night to night on groups of stars, by receiving the image of the group upon a photographic plate having a slow eccentric circular motion within the telescope, so that the images of the individual stars appear as circular traces upon the plate. Variations in the intensity of any trace, not common to all the linear images, indicate a variability of luminosity in the particular star describing the trace.—Prof. A. A. Rambaut read a paper on the distortion of photographic star images due to refraction.—The usual formulæ of refraction by which the relative position of one star with regard to another may be corrected for this effect, such as those published lately by the author in the *Astronomische Nachrichten*, No. 3125, are strictly applicable only to one definite instant of time. It is possible to keep only one star absolutely fixed on the plate by means of the slow motions in R.A. and declination, and the changes in the amount of the differential refraction will cause any other star to alter its position on the plate if the exposure is continued for any considerable time. The effect of this change is that all stars on the plate, except that used to guide by, are more or less distorted. The paper contains tables giving the amount by which the refraction changes at various declinations and hour angles, and from these the amount by which a star image on the plate is distorted in passing from any hour angle to any other can be readily computed. For instance, it is shown that an equatorial star whose distance and position angle from the guiding star are 1400″ and 45° would, in passing from an hour angle of 4h. to one of 5h., be distorted in R.A. by 5″·86 and in declination by 7″·98. It appears, however, that if the zenith distance does not exceed 60° and the exposure is limited to a quarter of an hour, the distortion will not exceed 0″·2, and that if the corrections are computed for the middle of the exposure and the measures made from the middle of the slightly distorted image no error will arise.—Prof. T. Johnson, exhibited *Gomontia polyrhiza*, Born. et Flah., a green alga, perforating the shells of various molluscs. Specimens were collected at different localities on the west and east coasts of Ireland; Galway (April, 1891) being the first locality in which the plant was observed.

PARIS.

Academy of Sciences, May 1.—M. Loewy in the chair.—The motion of liquids studied by chronophotography, by M. Marey. The water whose motion was to be studied was contained in a long tank bent into an elliptic shape and returning upon itself. One of the branches had both sides closed by panes of plate-glass, behind which was placed a screen of black velvet. A centimetre scale was fixed to the inner pane, and the tank was illuminated by sunlight reflected from below. The camera was placed at a distance in front of the glass, screens being arranged so as to keep off all light except that coming from the water. When the water was clear, the only thing photographed was the meniscus formed by its surface against the glass, which appeared as a bright straight line. When the surface was disturbed by waves, the nature of the disturbance was indicated by the successive shapes assumed by the meniscus. To study the internal motions of the liquid, small globules were constructed of wax and resin, silvered like certain pills, and so proportioned as to be slightly heavier than water, so that they could be made to float in neutral equilibrium by adding salt water. Stationary waves were then produced by rapidly changing the immersion of a solid cylinder on the opposite side of the tank, when the meniscus was thrown into the species of trochoidal curve already deduced from hydrodynamical theory. This curve appears in the photographs in great perfection. A wave of translation was also photographed fourteen times per second, and its velocity, as calculated by the scale, was 2·24 m. per second. Streams and eddies were also produced in the tank, and traced by means of the bright balls. On letting the water flow past an obstacle in the form of a fish, more obtuse on one side than on the other, it was proved that no perceptible eddies were formed if the water first encountered the obtuse side, but that it was greatly disturbed if the acute end was presented to the stream.—Determination of the specific heat of boron, by MM. Henri Moissan and Henri Gautier.—On mineral phosphates of animal origin, and on a new type of phosphorites, by M. Armand Gautier.—On the sanitary system adopted by the Dresden Conference for establishing common measures to safeguard the public health in times of epidemic cholera, without placing useless obstacles in the way of commercial transactions or the movements of travellers, by M. Bronardel.—Observations of the comets, Brooks (1892, VI.), Holmes (1892, III.), and Brooks (1893, I.), made with the great equatorial of Bordeaux, by MM. G. Razet, L. Picart, and F. Courty.—On a general case where the problem of the rotation of a solid body admits of uniform integrals, by M. Hugo Gyldén.—On the displacement of the temperature of maximum density of water by pressure, and the return to the ordinary laws under the influence of pressure and temperature, by M. E. H. Amagat.—Researches to establish the bases of a new method of recognising the adulteration of butter by margarine employed either singly or mixed with other fatty materials of vegetable or animal origin, by M. A. Houzeau.—Observation of the solar eclipse of April 16, 1893, at the observatory of the Société Scientifique Flammarion at Marseilles, by M Léotard.—On a class of differential equations, by M. Vessiot.—On the structure of finite and continuous groups, by M. Cartan.—On the ordinary differential equations which possess a fundamental system of integrals, by M. A. Guldberg.—On the reduction of the problem of tantochronics to the integration of a partial differential equation of the first order and the second degree, by M. G. Kœnigs.—On the densities and molecular volumes of chlorine and of hydrochloric acid, by M. A. Leduc.—On the diminution of the coefficient of expansion of glass, by M. L. C. Baudin.—On the systems of dimensions of electrical units, by M. E. Mercadier.—On the influence of longitudinal magnetisation upon the electromotive form of a copper-iron couple, by M. Chassagny.—Optical phenomena presented by secondary wood in thin sections, by M. Constant Houlbert.—Decomposition of oxalic acid by the ferric salts under the influence of heat, by M. George Lemoine.—Contribution to the study of the Leclanché cell, by M. A. Ditte. On the fluorides of the alkaline earths, by M. C. Poulenc.—On the quantitative determination of phosphoric acid, by MM. A. Villers and Fr. Borg.—On licarene derived from licareol, by M. Ph. Barbier.—On a vegetable nucleine, by M. P. Petit. On an earthquake shock felt at Grenoble on April 8, by M. Kilian.—The month of April, 1893, by M. E. Renou.—On the emission of a sugar-containing liquid by the green parts of the orange-tree, by M. E. Guinier.—On a new genus of conifers found in the Albian of the Argonne, by M. Paul Fliche.—Discovery of two skeletons at Villejuif and at Thiais, their age and ethnic character, by M. Zaborowski.—Periodic form of the doriferous power in the fatty series, by M. Jacques Passy.—Researches on the employment of tree leaves in the feeding of cattle, by M. A. Ch. Girard.

BERLIN.

Physiological Society, April 7.—Prof. du Bois Reymond, President, in the chair.—Dr. Engel gave an account of the outcome of his researches on the development of blood corpuscles. By using appropriate staining reagents, and fixation of the corpuscles by drying, he had found, in the embryos of mice in various stages of development and in leukhæmic children, that at first spheroidal nucleated cells make their appearance, metrocytes, which subsequently divide karyokinetically into daughter-metrocytes. From the latter some non-nucleated cells containing hæmoglobin are developed, as also some red-coloured cells, from which are then formed the red corpuscles, the nucleated white corpuscles and platelets. In the discussion which ensued Prof. Ehrlich confirmed the above results from personal observations, but regarded the origin of white blood-corpuscles from the red cells as not yet definitely established. Prof. Kossel spoke on a new saccharine substance called Dulcin, describing its chemical constitution and its effect on rabbits and dogs. Dulcin is two hundred times as sweet as sugar. Rabbits were unaffected by daily doses of 2 grm. (= 400 grm. sugar), but dogs were found to lose their appetite by prolonged taking of the above dose, recovering it soon when the drug was no longer administered.—Prof. Ewald had tried the effect of dulcin upon both healthy and sick people, observing no ill effect with doses equal to the amount of sugar ordinarily consumed. Prof. Heymans, of Ghent, reported that employing Golgi's method he had observed numerous branching nerves in the muscles of the wall of the cardiac ventricle, and particularly in the apex of the heart. Dr. Lilienfeld had studied the relationship of cell-elements to certain colouring matters, and exhibited a mixture of the latter, which appeared of an equally brownish-violet colour, both in aqueous and alcoholic solution. On shaking up in this crystals of nucleinic acid, the chief constituent of the nucleus, they were at once coloured bright green, whereas white of egg assumed an intense red colour.

April 21.—Prof. du Bois Reymond, President, in the chair.—Dr. Goldscheider reported upon experiments on the sense of touch in the blind, as made by Hocheisen on eight individuals, of whom some were born blind, while others became blind in early youth. The results obtained showed that the muscular sense of the blind is far more acute than of those who can see, being more acute in the youthful blind than in those who are older; in the latter the sense is scarcely more acute than that of those who can see. Similarly the power of localising was more acute in the young than in those who are older, and did not differ appreciably from that of those who can see. By practice both the above senses can be so sharpened in those who possess sight that they are ultimately as acute as for the blind.—M. Krüger spoke on the chemical constitution of adenin and hypoxanthin, and described the reactions which led to the establishing of their constitutional formulæ.

Physical Society, April 28.—Prof. Kundt, President, in the chair.—Prof. Neesen spoke on a new mercurial pump he had constructed on the principle of a Sprengel pump. Dr. Fröhlich developed his views on the theory of the electromagnet, which by bringing Hopkinson's theory into accord with conceptions of magnetic resistance and ideas on saturation had led to a considerable advance in generalisation. The discussion which ensued was chiefly taken up by Dr. Du Bois, who urged that the views propounded were rather of technical than scientific interest.

[*Note.*—In the report of the Physical Society (see NATURE, April 27, p. 624), in line five from the top, for "pressure" read "thickness," and in line six from the bottom for "Wren" read "Wien."]

DIARY OF SOCIETIES.

LONDON.

THURSDAY, MAY 11.

MATHEMATICAL SOCIETY, at 8.—On some Formulæ of Codazzi and Weingarten in Relation to the Application of Surfaces to each other: Prof. Cayley, F.R.S.—On the Expansion of Certain Infinite Products: Prof. L. J. Rogers.—A Theorem for Bicircular Quartic Curves and for Cyclides Analogous to Ivory's Theorem for Curves and Surfaces of the Second Degree: A. L. Dixon.—On the Linear Transformations between Two Quadrics: H. Taber.—The Collapse of Boiler-flues: A. E. H. Lowe.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—On the Prevention of Sparking, Compound Dynamos without Series Coils or Magnets; and Self-exciting Dnamos and Motors without Winding upon Field Magnets: W. B. Sayers.

ROYAL INSTITUTION, at 3.—The Atmosphere: Prof. Dewar, F.R.S.

FRIDAY, MAY 12.

PHYSICAL SOCIETY, at 5.—The Drawing of Curves from their Curvature: C. V. Boys, F.R.S.—The Foundations of Dynamics: Oliver Lodge, F.R.S.

ROYAL ASTRONOMICAL SOCIETY, at 8.

ROYAL INSTITUTION, at 9.—Isoperimetrical Problems: Lord Kelvin, Pres.R.S.

AMATEUR SCIENTIFIC SOCIETY, at 8.—Geological Time (with Special Reference to Mr. Mellard Reade's Paper in the *Geological Magazine* for March): W. H. Davis.

SATURDAY, MAY 13.

ROYAL BOTANIC SOCIETY, at 3.45.

ROYAL INSTITUTION, at 3.—Johnson and Swift: Dr. Henry Craik, C.B.

TUESDAY, MAY 16.

ZOOLOGICAL SOCIETY, at 8.30.—On the Atrium and Prostate of the Oligochætous Worms: F. E. Beddard, F.R.S.—Descriptions of Fifteen New Species of Pleurotomidæ: G. B. Sowerby.—List of Mammals inhabiting the Bornean Group of Islands: A. H. Everett.—On a Second Collection of Mammals sent by Mr. H. H. Johnston, C.B., from Nyassaland: O. Thomas.

FRIDAY, MAY 19.

ROYAL INSTITUTION, at 9.—Poetry and Pessimism: Alfred Austin.

SATURDAY, MAY 20.

ROYAL INSTITUTION, at 3.—Johnson and Wesley: Dr. Henry Craik, C.B.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—The Future of British Agriculture: Prof. Sheldon (W. H. Allen).—The Nests and Eggs of British Birds: C. Dixon (Chapman and Hall).—Theorie der Optischen Instrumente: Dr. S. Czapski (Breslau, Trewendt).—Practical Astronomy, 2nd edition: P. S. Michie and F. S. Harlow (K. Paul).—An Analytical Index to the Works of the late John Gould, F.R.S.: Dr. R. B. Sharpe (Sotheran).—The New Technical Educator, vol. 1 (Cassell)

PAMPHLETS.—Determinations of Gravity with Half-second Pendulums on the Pacific Coast, in Alaska, and at Washington, D.C., and Hoboken, N.J.: T. C. Mendenhall (Washington).—The Photoscope (Liverpool, Sanders).

SERIALS.—Medical Magazine, May (Southwood).—Quarterly Journal of the Geological Society, vol. xlix. Part 2, No. 194 (Longmans).—Journal and Proceedings of the Royal Society of New South Wales, vol. xxvi. (K. Paul).—Verhandelingen der Koninklijke Akademie van Wetenschappen te Amsterdam, Erste Sectie, Deel. 1, Nos. 1, 2, 4, 5, 6; Tweede Sectie, Deel. 1, Nos. 1, 4, 10 (Amsterdam, J. Müller).—Journal of the Chemical Society, May (Gurney and Jackson)—Proceedings of the Royal Society of Edinburgh, vol. xix. pp. 193-295 (Edinburgh).—Himmel und Erde, May (Berlin, Paetel).—Jahrbuch der k.k. Geologischen Reichsanstalt, Jahrg. 1892, xlii. Band 3 and 4 Heft (Wien).—Journal of the Scottish Meteorological Society, third series, No, ix. (Blackwood).—Proceedings of the American Academy of Arts and Sciences, new series, vol. xix. (Boston, Wilson).—Report of the Marlborough College Natural History Society, No. 41 (Marlborough).

CONTENTS.

THURSDAY, MAY 18, 1893.

OSTWALD'S GENERAL CHEMISTRY.

Lehrbuch der Allgemeinen Chemie. Von Dr. Wilhelm Ostwald. Band I. 1891, Band II. Theil I. 1893. Zweite Auflage. (Leipzig: Wilhelm Englemann.)

THE conception of molecule is essential in explaining the phenomena of both chemistry and physics. Porosity and compressibility point to the conclusion that matter does not entirely fill space, to account for the dispersion of light requires that matter should have a grained structure; these and countless other physical facts find an explanation in the conception of molecule. Moreover, from various observations, more especially on the properties of gases and the phenomena of surface tension, the size of molecules can be approximately calculated, and in terms of the idea of molecule deduced in ways such as these physical properties are explained.

The chemist, on the other hand, has arrived at the need of the conception of molecule from totally different considerations. In the early days of his science, when the laws of combining proportions and of chemical equivalents were taking definite shape, the revival of the conception of atom was of immediate service in furthering the progress of chemistry. It was not long in becoming apparent, however, that the conception of atom alone was insufficient to meet the facts.

The relative numbers of atoms entering into the composition of compounds was a matter of doubt until Avogadro's hypothesis was accepted, and until it was granted that definite groups of atoms—chemical molecules—were concerned in chemical processes.

The chemist has thus built up his conception of molecule in accordance with chemical facts; he regards it as a structure composed of parts, and in order to explain the existence of isomers, he has to assume definite relative arrangements of the atoms within a molecule.

From the fact that the two conceptions of molecule have been derived independently of one another, it has come about that physical properties are discussed more or less apart from the chemical nature of the substances examined, and for this reason within recent times there has arisen a fascinating field of inquiry on the borderland of chemistry and physics. For it has been urged, "Is it not possible to trace the cause of physical phenomena beyond the physical molecule?" If, as the chemist has shown, the molecule is a structure composed of parts, is it not possible that these parts of molecules are the units to be dealt with? In short, "Is not the ultimate cause of physical as well as of chemical phenomena to be ascribed to the chemical atoms and their mutual relationships?"

Already this question has been answered in several ways, and in none more striking than by those investigations which are concerned with the physical constants of substances and their chemical nature. Here it has been shown that the magnitudes of many physical constants are conditioned by the nature, number, and arrangement of the atoms which compose molecules and that frequently definite changes in chemical nature bring about definite quantitative changes in the magnitude of physical constants.

Books dealing with such investigations as these are but few, indeed the first volume of the book before us is practically the only one which gives a comprehensive view of what has been done in this direction. If we exclude those parts which are purely physical and which are concerned with familiarising the reader with the physical properties to be treated, the volume may in the main be taken as linking on the chemical to the physical conception of molecule, in so far as to show that the magnitudes of physical constants are functions of molecular weight and molecular structure.

The general arrangement of the contents of this volume is pretty much as it was in the previous edition, although very few pages remain as they were, and the introduction of recent investigations has increased the size of the volume by about one-third. The atomic hypothesis and the laws upon which it is based are first treated, then follows a useful summary of the various atomic weight estimations, from which are deduced the probable values of those fundamental constants, values which are already finding their way into current literature. The numerical relations existing between the atomic weights of the elements constitute the concluding portion of this the first of the six books into which vol. i. is divided. Succeeding books deal respectively with the physical properties of gases, liquids, solutions, and solids, and with the relations existing between the physical properties and the chemical nature of the substances.

Solutions are, in this edition, for the first time treated in a separate book, which with certain additions has been translated into English by Mr. Pattison Muir, and has already been noticed in these columns (NATURE, vol. xlv. p. 193). Electric conductivity and electrolysis now find a place in vol. ii. under electro-chemistry. The sixth and last book of vol. i. deals with chemical systematics—the criteria by which atomic weights are chosen, the periodic law and the relations between the physical constants of the elements and their atomic weights, and the molecular theory and the structure of chemical compounds in which the doctrines of valency, isomerism, &c., are discussed.

The peculiar interest which attaches to connections between the physical constants of substances and their chemical nature lies in the fact that an idea is thereby obtained of the constitution of the substances as they actually exist. Structure as deduced from purely chemical methods is founded upon reaction. The compound has to be decomposed before its constitution can be determined, and occasionally such methods lead to ambiguous results. Examples are steadily multiplying of compounds which in one reaction appear to correspond with one formula, while in another reaction a different formula better represents their chemical behaviour. Already measurements of physical constants have been applied to some such cases and have served to indicate that the structure of a pure substance may be conditioned by its temperature. At high temperatures, for example, acetyl acetone would appear to exist in the ketonic condition, $CH_3CO.CH_2.CO.CH_3$, while as temperature falls it would seem as if a gradual transition to the alcoholic conditions,

$CH_3.C(OH):CH.CO.CH_3$ and $CH_3.C(OH):C.C(OH)CH_3$, took place.

But physical methods can be applied to the study of the phenomena of chemical change as well as to those of chemical structure. Change of any kind taking place in material substances is to be sought in the nature of the energy associated with those substances, and chemical change has therefore to be sought in the nature of chemical energy. Of the nature of chemical energy, however, we know but little. Although it is the source of most of the energy turned to practical account in the arts and manufactures, and indeed, directly or indirectly, of all vital energy, it cannot be directly measured, and its nature is, as yet, but a matter for speculation.

Part 1 of vol. ii. of the "Lehrbuch" is concerned with making clear the present position of knowledge on this subject of chemical energy. To begin with, energy in general is discussed, the various forms under which it is known to us, and the units in which they are measured. Particular attention is directed to the factors which enter into the expressions denoting several of the types of energy, and more especially to the intensity factor. In the case of heat, for example, the intensity factor is temperature, and temperature, of course, determines whether heat energy shall be transferred from one body to another. A heat change between two bodies is conditioned by their temperature, and if the factors entering into the expression for chemical energy could be ascertained, the cause of chemical change might be traced in a similar way.

But although chemical energy cannot be directly measured, it can be transformed into other kinds of energy, and in turn other kinds of energy may pass into chemical energy. The amounts of these other kinds of energy which are thus involved in chemical processes are often capable of accurate measurement, and from such measurements alone can an insight into the nature of chemical energy be at present obtained. With such measurements the rest of the part is concerned.

During chemical change, chemical energy passes most readily and most completely into heat, and hence thermo-chemistry is first dealt with. A general historical discussion of the subject is succeeded by chapters on the non-metals, salt formation in aqueous solutions, the metals, and organic compounds. The concluding chapters deal with the "energetics" of heat, wherein is to be found the material which can be grouped around the second law of thermodynamics and the nature of heat energy in general, and with "chemical energetics" which treats of such attempts as have been made to arrive at the nature of chemical energy and its relations to heat energy. Where possible, connections between the chemical nature of substances and the heat energy to which they give rise during chemical change are pointed out, and the general application of thermal results to problems in chemical structure is kept well to the front.

The subject of electro-chemistry, which has been entirely recast, now occupies some 500 pages, as compared with little more than 100 in the first edition. It consists of a historical introduction, and of chapters on electrical energetics, Faraday's law, the migration of the ions, the conductivity of electrolytes, the constitution of electrolytes and the properties of ions, electromotive force, the differences of potential in cells, and on electrolysis and polarisation. In this section the author has collected and generalised the mass of communications which have recently been brought into existence by the fruitful hypothesis of electrolytic dissociation, and has connected them up with previous knowledge on the electrical properties of solutions. In conjunction with other portions of the "Lehrbuch" on the stoichiometry of solutions, this section gives the only full and systematic account of the new theory of solutions which is available to the general reader.

The third and last book of this part takes up the subject of photo-chemistry. The nature of radiant energy, which plays so important a part in the economy of nature and its relations to chemical energy, are first discussed. Then follow chapters on actinometry, the law of photochemical action, and on special photo-chemistry, which deals with the assimilation of carbon by plants, and the action of light on various chemical substances.

Enough has been stated to show that the work is unique. There is no other book which even attempts to cover the same ground. No chemical library can be regarded as complete without a copy of Ostwald's "Lehrbuch." It contains an enormous amount of information, both theoretical and practical, which is simply indispensable to the chemist and to the physicist. It is, indeed, difficult to overestimate the value of such a work.

But at the same time, mainly for the reason that it touches upon so many subjects, its usefulness in certain directions may to some extent be interfered with. One cannot fail to notice that the character of the work frequently savours more of a dictionary than a handbook. In the chapters on solutions and electro-chemistry there is, perhaps, not much room for this objection, for there the author has a definite purpose in view—the elucidation of the "new theory"—and writes around it, moulding his information and shaping the issues in a way that leaves little to be desired, if his standpoint be granted. Contrasted with the treatment of these sections we have on the other hand, that of the book generally. Here are set out short abstracts, in many cases but fragmentary, of the more important researches on the subject under discussion, but little attention being paid however to generalising the results or smoothing down the discrepancies, or indeed the contradictions which occasionally arise. For example, under the subject of the molecular volumes of liquids Kopp's work comes first, and his method of obtaining atomic volumes is given, the values of carbon and hydrogen being derived by the comparison of aromatic and fatty compounds. In due course Horstmann's conclusion that the ring-grouping of atoms exerts a marked effect on molecular volume finds a place, and the author passes on to other researches. But if Horstmann's conclusion is justified the whole superstructure of Kopp's calculated atomic volumes is subject to modification, as the effect of ring-grouping is ignored in the derivation of his atomic constants. Again, here as elsewhere, the author gives Schröder's work the prominence which has been more or less denied it in the past. Schröder's method, however involves different atomic constants to those of Kopp, and it is left almost entirely to the reader to assess the relative worth of the two systems. On one page of this chapter, too, Schiff's rule relating to the boiling points and molecular volumes of isomers is given, while two pages later are set out the results of Städel, which lead to the opposite conclusion, a conclusion which is much more generally true than that of Schiff, as the reader may verify by referring to the tables of physical constants given towards the end of the chapter.

The author may purposely have left matters in this condition, his idea being merely to indicate the gist of what has been done on the different questions. Indeed the present condition of subjects like molecular volume is so unsatisfactory as to prevent any very definite conclusions being stated. Nevertheless, if such abstracts as are given had on various occasions been supplemented by a statement of opinion as to the nett upshot of the whole discussion, there is little question that the average student would have found the mastering of several portions of the "Lehrbuch" a task of less difficulty than at present it is.

On p. 387, lines 2, etc., a volume-change due to oxygen is attributed to hydrogen: typographical errors are somewhat numerous, as could hardly be otherwise in a work of this kind.

To complete the second edition of the "Lehrbuch," Part 2 of the second volume, which treats of chemical affinity, has still to be published. Its appearance will serve to complete a work which goes further than any other to show how chemistry and physics must be united in the endeavour to arrive at the real nature of material phenomena.

J. W. Rodger.

CLARK ON THE STEAM ENGINE.

The Steam Engine: a Treatise on Steam Engines and Boilers. By Daniel Kinnear Clark, M.Inst.C.E. (London, Glasgow, Edinburgh and New York: Blackie and Sons, Limited, 1892.)

THE author of this book holds the first place among those who many years ago made the locomotive an object of scientific study. His famous work on railway machinery is still of prime importance, holding as it does an honoured place in many drawing offices. The present work consists of two ponderous volumes of some 800 pages each, and claims to be a comprehensive, accurate, and clearly written text-book, fully abreast of all the recent developments in the principle, performance, and construction of the steam engine. This no doubt is a very large claim to make for any work, but when one remembers who the author is, one is bound to admit that no one is more capable of carrying out so important a scheme.

Besides the author's many researches in locomotive engineering particularly, we notice that the numerous published records of investigation and practice have been made use of. This is certainly as it should be, and having been judiciously done adds greatly to the value of the work as a book for reference.

The work is divided into four main sections:—(1) The principles and performance of steam boilers; (2) the principles and performance of steam engines; (3) the construction of steam boilers; (4) the construction of steam engines. These main sections are again subdivided into many chapters.

The vast amount of information to be gathered from these pages may be imagined when it is noted that the first section alone takes up some 373 pages. Most of this space is absorbed by descriptions of experiments with special types of boilers, mechanical and other means of stoking, the prevention of smoke and the relative efficiency of various kinds of coal. Besides this the properties of steam are discussed, and the question of the economical combustion of fuel is very thoroughly gone into. The second section is an excellent treatise on the general behaviour of steam in the cylinder, and here we find evidence of the great experience of the author in this subject, particularly in the handling of the indicator diagram and the many lessons to be learnt from it when properly understood. The third section deals with the construction of steam boilers and concludes the first volume. Here we find a collection of reports and original matter of a valuable description embracing the whole subject. It is a pity that the classical researches of the late Mr. P. W. Willans find no place in the volume, because he, of all engineers, studied the thermodynamics of steam thoroughly, and his contributions to science on this subject are invaluable. It may be noted that his central valve high-speed engines find no place in the work. This also is to be regretted, because this type of engine is rapidly coming to the front, both as an economical machine and a trustworthy motor particularly for electric lighting by direct driving, the Glasgow Corporation Electric Lighting Station being among the latest to be fitted with these engines.

The first volume may be roughly said to contain most of the theoretical part of the subject, and the second volume the description of many types of stationary, marine, and locomotive engines. This volume begins with a very complete description of the various valve gears in use and the distribution of steam by ordinary and other slide valves, also the construction and modes of working of the many governors in use. Further on stationary engines for general purposes are described and very fully illustrated. We miss from these excellent examples the many types of high-speed engines used for driving dynamos, centrifugal pumps, fans, &c. Many of these have reached a high state of efficiency and might have been included with advantage.

Chapter lx. deals with British and foreign types of locomotives. We are not surprised to find that the many chapters on the locomotive are by far the best in the whole work. The author may be said to have grown up with the locomotive and to have made it his own particular study; to this day the plucky man who rode on the buffer beams of the old Edinburgh and Glasgow four-wheeled engines taking indicator diagrams is often quoted on that line, now part of the North British system.

The paper read by the late Mr. William Stroudley on the construction of locomotive engines, &c., before the Institution of Civil Engineers contains probably the most recent and trustworthy information at present available on this subject. The author has done well in making the quotations he does from this source. Of the British locomotives illustrated all are of most recent design. The table of types of American engines made by the Baldwin locomotive works is interesting, and the illustrations are good; but what is the use of giving the reputed weight of trains hauled without quoting the average speed? Surely the one can be of little service without the other. Continental locomotive practice is well represented in the types in use on the St. Gothard railway. Of peculiar types of locomotives perhaps the six-coupled double bogie Fairlie engine is a good example. This engine, designed by Sir Alexander M. Rendel for the Mexican Railway Company, is stated to be able to haul a train weight of 3600 tons on the level. The engine when fully charged carries 2850 gallons of water, and has 300 cubic feet of room for coal, and weighs 92¼ tons. On regular duty the engines run on a section of road which, for a length of fourteen miles, has many gradients of 1 in 25, with curves of 350 feet radius. More recent Fairlie engines supplied to this company weigh 93 tons 16 cwt. in running order, and are reported to do their work admirably.

We now come to the description of the different types of compound locomotives in use. These are practically all included in the Webb and Worsdell types in use in this country. Of the Webb type we find the Dreadnought class, and, in the appendix, the Greater Britain, thoroughly described and well illustrated.

At the present time the London and North-Western Railway Company have eighty-three compound locomotives of Mr. Webb's design at work, the total mileage of which since 1882 up to the end of December, 1892, was 22,854,037 miles, with an average consumption of 35·1 lbs. of coal per mile. This includes not only the fuel consumed in actually working the train, but also 1·2 lbs. used in raising steam and all fuel consumed whilst the engine is standing or shunting. The description of the Worsdell type of compound is equally clear, and is well illustrated by the Great Eastern and North Eastern locomotives. Why, however, are the Worsdell intercepting and starting valves alone described and illustrated? when this type of valve is seldom if ever used outside the North-Eastern Railway, the Worsdell Von Borries, Lapage, disc automatic valve being generally adopted in its place. Sixty Worsdell compound goods engines of the Mogul type have recently been sent to India, the cylinders being respectively 20 inches and 28 inches in diameter, stroke 26 inches, and the coupled wheels 5 feet 1½ inches in diameter. These engines and tenders weigh about 95 tons in running conditions.

In the addenda to the second volume there is some interesting information in reference to the construction of American locomotives and boilers, and details are freely illustrated. Following this is a description of the Vauclain compound locomotive as made by the Baldwin locomotive works. Then comes a short description of the Westinghouse brake—a very good break no doubt; but why should not the Vacuum brake find a place in the volume?

These volumes cannot of course be appreciated without careful study. They are a perfect mine of information, partly original, partly derived from contributions to the proceedings of various technical institutions and societies. The illustrations are excellent, and the typography remarkably clear. The work should be welcomed, both by the student and the engineer, as the best text-book on the steam engine and boiler yet published.

N. J. LOCKYER.

A LIFE OF LOUIS AGASSIZ.

Louis Agassiz: his Life and Work. By Charles Frederick Holder, LL.D., &c. (Leaders in Science.) (G. Putnam's Sons, New York and London.)

WITHOUT a Life of Louis Agassiz a series of histories of leaders in science would be incomplete. Fortunately materials are not lacking, for in addition to the "Life and Correspondence" edited by his widow, there are numerous sketches and accounts of particular aspects of the man. The present volume tells the main incidents of his life and work, pleasantly and succinctly, and presents us with a clear outline of a remarkable personality. The book is well printed and the illustrations are not few. Some are good, others are not specially connected with the text, two are failures. Both relate to Switzerland. One is a sensational picture of Agassiz' "descent into the heart of a glacier," where he is being lowered down into a crevasse, while the text clearly shows that he descended a *moulin*. The other represents "Agassiz on the pinnacle of the Jungfrau." We think that this must be a studio composition, for the "pinnacle" is not very like what we have seen, and the topography of the view is incomprehensible.

Agassiz was a sturdy Swiss lad, uniting, as became a Neuchâtelois, something of French versatility with German tenacity of purpose; a close and keen observer delighting in every aspect of nature, happily neither "crammed" nor forced as a boy. When only twelve years old he was an omnivorous collector, and was more than this, a close student of his treasures.

Intended for commerce, he prevailed upon his parents to let him attend a course of classes at the University of Lausanne, then to proceed to Heidelberg and Munich as a student of medicine. At the age of twenty-three he had obtained the degree of doctor in that faculty as well as in philosophy. By this time, however, he had determined to devote himself to science, having already made his mark by his work on fresh-water fishes. After some stay in Paris a professorship was ultimately created for him at Neuchâtel, which he held until a visit to America ended in his accepting a post at Cambridge, Massachusetts, and settling down in the United States. But before leaving his native land he had become famous also by his studies of glaciers; still it was in the New World that the most important part of his life's work was done. Apart from the immense impulse which he gave to the progress of science in the United States, his explorations along the coast of Florida, in Brazil, on both coasts of South America, all supplied abundant material for study, which was worked up with unflagging industry.

The book, in short, is a marvellous record of work accomplished. We read in it of incessant labours in the lecture-room, the laboratory, and the field, yet the list of his books and scientific papers appended to this volume is perfectly appalling. Of the former there are thirty-nine, large and small; the list of the latter occupies twenty-two and a-half pages, each containing about ten entries, on the average. But this incessant activity, mental and physical, wore out even the sturdy Switzer, careful as he had always been in exercising the body. Cuvier's last words to him, "Be careful, and remember that work kills," had been, perhaps of necessity, neglected. The day after they were spoken the great naturalist had been stricken to death by paralysis. They were equally prophetic in the case of Agassiz, for by his sixty-seventh year even his vigorous constitution was worn out.

Agassiz was a born teacher. As one of his admirers says, "His greatest work in science was his influence upon other men." Surely this is one of the best of epitaphs. This memoir contains some pithy sayings worth remembering in our generation. These are a few samples—"It is a false idea to suppose that anybody is competent to learn or to teach anything;" "The mind is made strong not through much learning but by the thorough possession of something;" "Learn to read the book of Nature for yourself;" "Train your pupils to be observers;" "It is better to have a few forms well known than to teach a little about many hundred species;" "The study of Nature is an intercourse with the highest mind." A remark, also of his, has a lesson for this age of many books, when he said, commenting on his early difficulties in obtaining them, that "he believed it had been really an advantage, for it prevented him from relying too much on them, their absence forcing him to investigate for himself."

Dr. Holder compares the influence of Agassiz in America with that of Darwin in England. It was in many respects very different, as were the men; yet they had much in common: the same intense love of nature, the same thirst for knowledge, the same indomitable energy in the pursuit of it. They were alike in being seriously hampered: Agassiz by poverty, at any rate in the earlier part of his life, for many a time his mind had to be fed at the expense of his body; Darwin by ill health in the larger and later part. Yet they were very different: the one in constant intercourse with his fellow men, the enthusiastic leader of a band of students, the centre of a society; the other compelled to lead a recluse life. They looked also upon nature from different standpoints. Agassiz was unable to accept Darwin's views as to the origin of species, though it is curious to see what concessions he was prepared to make in regard to a progression from an embryonic stage to one of high development. This, however, must be by successive creations, not by evolution. In regard to the latter he apparently shared the fears of not a few other religious men, and failed to see that the vision of Mother Carey in Peacepool, "making things make themselves," may be as full an expression of the operation of a Divine Mind as any scheme of creation.

Agassiz, though he had a hard struggle, was fortunate in many respects: in the possession of good parents, a vigorous frame, and a sound constitution; above all, in acquiring the friendship of such men as Cuvier and Humboldt at the age when their help was most needed. He was happy, like Darwin, in his family life, with a wife who was a helpmate, and a son who followed his footsteps, and still does honour to the name. Like Darwin also, he was *felix opportunitate vitæ et mortis*. Both had their obstacles to overcome, and their difficulties to conquer, but they would have found these more formidable, because more insidious, in the present generation. Is an Agassiz or a Darwin any longer a possible product? Natural science is now sometimes in danger of becoming a department of literature or a branch of physics. These men went to nature for their teaching rather than to books: now they would find it hard to avoid being smothered with "the literature of the subject," and being choked with the dust of libraries. To read the life of the genuine lover of out-door nature such as Agassiz or Darwin, is like a breath from a glacier in the valley of the Rhone; to study the record of a life so simple, so earnest, so pure, so reverent, is a lesson for all time.

T. G. BONNEY.

OUR BOOK SHELF.

Beiträge zur Biologie und Anatomie der Lianen, im Besonderen der in Brasilien einheimischen Arten. Von Dr. H. Schenck. Zweiter Theil. Beiträge zur Anatomie der Lianen. 8vo. pp. 271, tt. 12. (Jena: Gustav Fischer, 1893.)

IN a brief notice of the first part of Dr. Schenck's "Beiträge" (NATURE, vol. xli., p. 514), the fact that it was only the first part was overlooked; hence the remark that all the plates of that part were devoted to the illustration of the external morphology of chiefly woody climbers loses the force it would have had, had it referred to the whole work. The second part has now appeared, and this treats of the anatomy, whilst the first treats of the biology of this class of plants. The two volumes form a valuable book of reference on this subject; and the illustrations include examples of the anatomy of the stems of climbing plants belonging to about twenty-five natural orders. There are twelve large folded plates containing 178 figures, all very laboriously and carefully drawn. The Sapindaceæ and Leguminosæ are most numerously represented, and present some highly curious structures.

W. B. H.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Late Solar Eclipse.

IN his account of the work of the Eclipse Expedition at Fundium Mr. Fowler seeks to explain his inability to obtain the photographs at the moment of totality by the assumption that he received the signal of the beginning of totality at least ten seconds too late, and he bases this assumption on his own estimate of the difference in time which elapsed between my signal and that of M. Coculesco, one of the French observers at Fundium.

I did not hear M. Coculesco's signal, as my head was necessarily enveloped in the dark cloth of my photometer at the moment, but M. Deslandres, the chief of the French party, with whom I returned to Europe, tells me that he estimated the interval at about two seconds, with which estimate M. Coculesco concurs.

There would seem to be good reason to believe that the actual time of the total phase was several seconds less than we had been led to expect. The chronometer observations at Fundium (lat. 14° 7′) gave 243 seconds. M. Bigourdan, who was specially charged by the Bureau des Longitudes to make accurate observations on this point at Joal, which is a few miles to the west of Fundium, and in lat. 14° 9′, informs me that the total phase there was 241 seconds.

It is possible, therefore, that Mr. Fowler's estimate of 10 seconds may not only have been erroneous in consequence of the known difficulty of accurately estimating a time interval

during the exciting conditions of an eclipse, but may also have arisen from the fact that the actual eclipse was shorter than the calculated one.
T. E. THORPE.

Daylight Meteor, March 18.

THIS meteor, reported to NATURE by Dr. Rorie of Dundee, was also seen by Mr. A. G. Linney at Ackworth, near Pontefract. Careful comparison of their records gave a probable path from just S.E. of Lanark to 30 or 40 miles W. of Mull. Notes received later from the Fort William Low Level Observatory make it probable that the end was nearer there, say just N. of Mull. The former gives an actual path of 180 miles, from a height of 140 to 42 miles; the latter, 140 miles, ending at a height of 40 miles or less. If Dr. Rorie's time is correct, it travelled at a rate of 36 or 28 miles per second, both being rapid. This accounts for the magnificent streak. As this floated across to Dundee in three quarters of an hour, the central part must have in that time travelled 95 or 85 miles at a height of 100 to 90 miles above the earth, and in an E.N.E. direction. Thus its velocity seems to have exceeded 100 miles an hour. The Krakatão dust reached us in the same direction, its greatest height being 30 to 40 miles, and speed 72 miles per hour. A greater speed at greater altitude quite agrees with theoretical probabilities, although the increase seems very great.
J. EDMUND CLARK.

Roche's Limit.

A LETTER has been addressed by Mr. D. D. Heath to the Editor of NATURE on the statical problem involved in "G. R.'s" approximate method of finding Roche's limit. This letter has been submitted to me, and I have thus been led to look more closely into "G. R.'s" proof, which I adopted in a recent letter to NATURE (April 20, 1893, p. 581). Mr. Heath shows that both "G. R." and I have omitted the factor 2 from our result, and I now see besides that a statical solution is insufficient for the problem in question.

The problem may be stated thus :—To find at what distance two equal spheres in contact can revolve in a circular orbit round a third, the centres of the three spheres being in a straight line.

Take the following notation :—The single sphere of density σ and unit radius; the two spheres each of unit density and radii r; c, the distance from the centre of the single sphere to the point of contact of the two; and ω the angular velocity of the system.

The problem may be rendered statical by introducing the conception of centrifugal force estimated from the centre of inertia of the system, which is also the centre of rotation. The distance of the centre of inertia from the point of contact of the two spheres is $c\sigma/(\sigma+2r^3)$.

Then the three equations, only two of which are independent, which express the equilibrium of the spheres are :—

$$\omega^2\left(\frac{c\sigma}{\sigma+2r^3}+r\right)=\frac{\frac{4}{3}\pi\sigma}{(c+r)^2}+\frac{\frac{4}{3}\pi r^3}{(2r)^2},$$

$$\omega^2\left(\frac{c\sigma}{\sigma+2r^3}-r\right)=\frac{\frac{4}{3}\pi\sigma}{(c-r)^2}-\frac{\frac{4}{3}\pi r^3}{(2r)^2},$$

$$\omega^2\left(c-\frac{c\sigma}{\sigma+2r^3}\right)=\frac{4}{3}\pi r^3\left(\frac{1}{(c+r)^2}+\frac{1}{(c-r)^2}\right).$$

Adding the first two of these and dividing by $\frac{2}{3}\pi\sigma$, and then subtracting the second from the first and dividing by $\frac{2}{3}\pi r$, we have

$$\frac{3\omega^2}{\pi}\left(\frac{c}{\sigma+2r^3}\right)=\frac{4(c^2+r^2)}{(c^2-r^2)^2},$$

$$\frac{3\omega^2}{\pi}=1-\frac{8c\sigma}{(c^2-r^2)^2}.$$

Eliminating ω^2 we have

$$c(c^2-r^2)^2-8c^2\sigma=4(c^2+r^2)(\sigma+2r^3),$$

or

$$c^5-2c^4r^2-c^2(12\sigma+8r^3)+cr^4-4r^2(\sigma+2r^3)=0,$$

a quintic for determining c, the approximation to Roche's limit. If the two spheres are infinitely small compared with the single one, this reduces to

$$c^3=12\sigma.$$

Thus the factor 16 (which, as Mr. Heath shows, should have been 8) of "G. R.'s" and of my previous letter must be replaced by 12, when the rotation is taken into account. In the notation used before, we therefore have as the approximation to Roche's limit

$$2{\cdot}29\text{R}\times\left(\frac{\text{D}}{d}\right)^{\frac{1}{3}}.$$

Proceeding further, as I did before, to find when three homogeneous spheres are in contact, so that $\sigma=1$ and $c=2r+1$, we have—

$$22r^5-25r^4-60r^3+14r^2+38+11=0.$$

Unity is a solution of this, so that three equal spheres are in contact—an obviously correct solution.

There is another root with $r=2{\cdot}08$, so that the two spheres are each much larger than the third.

These solutions of course give no approximation to that of the problem to which the latter part of my letter referred.

May 3.
G. H. DARWIN.

The Use of Ants to Aphides and Coccidæ.

MR. COCKERELL is not quite accurate in saying that I have "adduced the production of honey-dew by aphides as a difficulty in the way of the Darwinian theory" (NATURE, vol. xlvii. p. 608). In the passage to which he alludes I have said, that the relationship which in this matter subsists between ants and aphides is one of the very few instances where it can be so much as suggested that the structures or instincts of one species have exclusive reference to the needs of any other species. Therefore, even if this suggestion were not thus opposed to all the analogies of organic nature, "most of us would probably deem it prudent to hold that the secretion must primarily be of some use to the aphis itself, although the matter has not been sufficiently investigated to inform us of what this use is" ("Darwin and after Darwin," p. 292).

But my object in now writing is to corroborate Mr. Cockerell's explanation. For, on looking up my references, I find a letter from the Rev. W. G. Proudfoot, dated March 26, 1891, in which he communicates the following observations :—

"On looking up I noticed that hundreds of large black ants were going up and down the tree, and then I saw the aphides. . . . But what struck me most was that the aphides showered down their excretions independently of the ants' solicitations, while at other times I noticed that an ant would approach an aphis without getting anything, and would then go to another. I was struck with this, because I remembered Mr. Darwin's inability to make the aphides yield their secretion after many experiments. A large number of hornets were flying about the tree, but seemed afraid of the ants; for when they attempted to alight, an ant would at once rush to the spot, and the hornet would get out of its way."

From this it seems probable that, but for the presence of the ants, the aphides would have been devoured by the hornets. It also appears that Darwin's explanation is likewise true, viz. that the aphides are bound to get rid of their excretions in any case, and therefore that "they do not excrete solely for the benefit of the ants."
GEORGE J. ROMANES.

Christ Church, Oxford, May 6.

MR. COCKERELL'S letter (NATURE, vol. xlvii. p. 608) suggests the possibility that the following fact bearing on the connection between a coccid and another member of the Aculeate Hymenoptera may be interesting. I have a quantity of *Cotoneaster microphylla* covering a long sunny bank, and this shrub is much infested by a coccid, *Secanium ribis*. The queen wasps (usually early in June, but this year they are beginning now) are attracted in great numbers by the secretion from the coccid and may be taken with a common ring net and destroyed, to the great advantage of my garden. As to the visits of the wasps being of any advantage to the coccid I am somewhat sceptical, though no doubt they are to the wasps—when they are not caught!
ALFRED O. WALKER.

Nant y Glyn, Colwyn Bay, May 5.

ON THE EARLY TEMPLE AND PYRAMID BUILDERS.

I HAVE in previous articles discussed the orientation of many temples in various parts of Egypt. It will have been seen that it has been possible to divide them into solar and stellar temples, and that in the case of the former both solstices and equinoxes have been in question.

I have also referred to the very considerable literature which already exists as to the pyramids, and shown how the most carefully constructed among them are invariably oriented truly to the four cardinal points, and further that it is possible that some parts of their structures might have served some astronomical purpose, since astronomical methods must certainly have been employed in their construction.

It has also been suggested that the fundamental difference between solstitial and equinoctial worships indicated by the solstitial temples and the pyramids required nothing less than a difference of race to explain it. I propose now to inquire if there be any considerations which can be utilised to continue the discussion of the question thus raised on purely astronomical grounds. It is obvious that if sufficient tradition exists to permit us to associate the various structures which have been studied astronomically with definite periods of Egyptian history, a study of the larger outlines of that history will enable us to determine whether or not the critical changes in dynasties and rulers were or were not associated with critical changes in astronomical ideas as revealed by changes in temple-worship. If there be no connection the changes may have been due to a change of idea only, and the suggestion of a distinction of race falls to the ground.

In a region of inquiry where the facts are so few and difficult to recognise among a mass of myths and traditions, to say nothing of contradictory assertions by different authors; the more closely we adhere to a rigidly scientific method of inquiry the better. I propose to show, therefore, that there is one working hypothesis which seems to include a great many of the facts, and I hope to give the hypothesis and the facts in such a way that if there be anything inaccurately or incompletely stated it will be easy at once to change the front of the inquiry and proceed along the new line indicated.

I may begin by remarking that it is fundamental for the hypothesis, that the temples of On or Heliopolis, as stated by Maspero and other high authorities, existed before the times of Mini (Menes) and the pyramid builders, whatever may have been the date of the original foundation of Thebes.

Before Mini, according to Maspero, "On et les villes du Nord avaient eu la part principale dans le développement de la civilisation Égyptienne. Les prières et la hymnes, qui formèrent plus tard le noyau des livres sacrés, avaient été ridigés à On."[1]

The working hypothesis is as follows :—

1. The first civilisation as yet glimpsed in Egypt, represented by On or Heliopolis, was a civilisation with a solstitial solar worship associated with the rise of the Nile. A northern star was also worshipped.

2. Memphis (possibly also Sais, Bubastis, Tanis, and other cities with east and west walls) and the pyramids were built by an invading race from a land where the worship was equinoctial. A star rising in the east was worshipped at the equinox.

3. The blank in Egyptian history between the sixth and eleventh dynasties was associated with conflicts between these races, which were ended by the victory of the representatives of the old worship of On. After them pyramid building ceased and solstitial worship was resuscitated; Memphis takes second place, and Thebes, a southern On, so far as solstitial solar worship is concerned, comes upon the scene as the seat of the twelfth dynasty.

[1] "Histoire ancienne," p. 41.

4. The subsequent historical events were largely due to conflicts with intruding races. The intruders established themselves in cities with east and west walls, and were on each occasion driven out by solstitial solar worshippers who founded dynasties (eighteenth and twenty-fifth) at Thebes.

1.—*On.*

I have taken another occasion of remarking how the various worships at Thebes were reflected in the orientation of the temenos walls. The so-called "symmetrophobia" of the Egyptians was full of meaning, which in this case, at all events, is no longer hidden. If we note this reflection, as we can over and over again, where both temples and walls still stand, it is fair to assume that where the walls alone remain the temples which they once enclosed, long since destroyed, had the same relation. These considerations, alas, have to be appealed to in the case of Heliopolis, to say so far nothing of Abydos and Memphis.

At Heliopolis the so-called "symmetrophobia" as indicated by the trend of the mounds given in Lepsius's plan, is so strong that in spite of the fact that only one obelisk of one temple remains, it is easy to show that both solstitial solar worship and star worship were carried on, if walls had the same relation to the included temples at On as they had at Thebes.

The solar temple at On has entirely disappeared. As may be gathered from the remains of the mounds, it lay in the line of the solstices. As the gods included Rā, Atmu, and Osiris, probably like the temple of Amen Rā at Thebes there were two temples back to back. At Thebes the temples were directed north-west—south-east, at On south-west—north-east.

My observations of the orientation of the obelisk show that the temple of which it formed part may have possibly been the first of the series which includes the temple of Mut at Thebes, and other temples, there and at Abydos; that is the worship of Set was in question, to speak generically. Now, according to Maspero,[1] Sit or Set formed one of the divine dynasties, being associated with the sun and air gods at On, *i.e.* with Rā, Atmu, Osiris, Horus, and Shou.

At Abydos, as also can be determined by the orientation of the walls, one of the oldest temples was probably a solstitial one. The stellar temples sacred to Set were built much later than the solar temple.

Like On, Abydos was a sacred city.[2]

"C'est comme ville sainte qu'elle était universellement connue. Ses sanctuaires etaient célèbres, son dieu Osiris vénéré, ses fêtes suivies par toute l'Égypte; les gens riches des autres nomes tenaient à honneur de se faire dresser une stèle dans son temple."[3]

If it be found that the references to "ancestors," and "divine ancestors," occur after the eleventh dynasty, the race represented by On may be referred to (see the articles on the Egyptian year), and it may be that so often referred to as the Hor schesu.

Only one star temple, as I have said, is still represented at On; those at Abydos are known to be late. The term, then, of Sun-worshippers was highly distinctive, and there is reason to believe that the stellar observations were connected with the solar worship.

2.—(*a*) *The East and West Walls and Pyramid Builders.*

On the hypothesis these came from a country where the worship was equinoctial.

We are justified from what is known regarding the rise of the Nile as dominating and defining the commencement of the Egyptian year that other ancient peoples placed under like conditions would act in the same way.

Now what the Nile was to Egypt the valleys of the

[1] *Op. cit.* p. 33.
[2] Maspero, *op. cit.*, p. 21.
[3] It is important to inquire if this took place after the advent of the eleventh dynasty.

Tigris and the Euphrates were to the early Chaldæan empire. Like the Nile, these valleys were subject to annual inundations, and their fertility depended, as in Egypt, upon the manner in which the irrigation was looked after.

But unlike the Nile, the commencement of the inundation of these rivers took place near the vernal equinox; hence the year, we may assume, began then, and, reasoning by analogy, the worship in all probability was equinoctial.

A people entering Egypt from this region, then, would satisfy one condition of the problem, but is there any evidence that this people built their solar temples and temple walls east and west, and that they also built pyramids?

There is ample evidence, although, alas! the structures in Chaldæa, being generally built in brick and not in stone, no longer remain, as do those erected in Egypt. Still, in spite of the absence of the possibility of a comparative study, research has shown that in the whole region to the north-east of Egypt the temenos walls of temples and the walls of towns run east and west; and though at present actual dates cannot be given, a high antiquity is suggested in the case of some of them. Further, the temples which remain in that region where stone was procurable, as at Palmyra, Baalbec, Jerusalem, all lie east and west. But more than this, it is well known that from the very earliest times pyramidal structures, called ziggurats, some 150 feet high, were erected in each important city. These were really observatories; they were pyramids built in steps, as clearly shown from pictures found on contemporary tablets; and one with seven steps and of great antiquity, it is known, was restored by Nebuchadnezzar about 600 B.C. at Babylon.

A second condition of the hypothesis is therefore satisfied.

But did this equinox-worshipping, pyramid-building race live at anything like the time required? Prof. Sayce showed in the Hibbert lectures which were delivered in the year 1887 that recent finds have established the existence of a King Sargon I. at Agade in Chaldæa 3800 B.C. Hence it seems that a third condition of the hypothesis is satisfied by this recent discovery. There was undoubtedly an equinox-worshipping, pyramid-building race existing in Chaldæa at the time the Egyptian pyramids are supposed to have been built.

Hommel, in a recent paper on the Babylonian origin of Egyptian culture, shows that the names of the gods corresponded in many cases with the names of deities mentioned in the oldest Egyptian pyramid texts. . . . The names were represented by exactly the same signs in both Babylonian and Egyptian hieroglyphics . . . the name and signs of Osiris the Babylonian Asari are represented in both countries by an eye. He contends that there had been a direct communication between the two civilizations, and that the Babylonian was the older of the two.

Next let us return to Egypt.

We find at Memphis, Sais, Bubastis, and Tanis east and west walls which at once stamp those cities as differing in origin from On, Abydos, and Thebes, where, as I have shown, the walls trend either north-west—south-east or north-east—south-west.

For Memphis, Sais, and Tanis, the evidence is afforded by the maps of Lepsius. For Bubastis it depends upon the statement of Naville, that the walls run "nearly from east to west," and with the looseness too often associated with such statements, it is not said whether true or magnetic bearings are indicated.

Associated with these east and west walls there is farther evidence of great antiquity. Bubastis, according to Naville,[1] has afforded traces of the date of Cheops and Chephren, and it is stated by Manetho to have existed as early as the second dynasty.

[1] "Bubastis," preface, p. iv.

It is also generally known that the pyramids in Egypt are oriented east and west. Nor is this all.

One of the oldest, if not the oldest, pyramid known, is a step pyramid modelled on the zuggurat pattern: the so-called "step pyramid of Sakkarah." The steps are six in number, and vary in height from thirty-eight to twenty-nine feet, their width being about six feet. The dimensions are (352 north and south) × (396 east and west) × 197 feet. Some authorities think this pyramid was erected in the first dynasty by the fourth king (Nenephes of Manetho, Āta of the tablet of Abydos.) The arrangement of chambers in this pyramid is quite special.

The claim to the highest antiquity of the step pyramid is disputed by some in favour of the "false pyramid" of Mêdûm. It also is really a step pyramid 115 feet high; its outline, which conceals some of the steps, shows three stages, seventy, twenty, and twenty-five feet high; but in its internal structure it is really a step pyramid of six stages.

This pyramid must, according to Petrie, be attributed to Seneferu; but De Rougé has given evidence to the contrary.[1] Seneferu was a king of the fourth dynasty.

We have at Dashour the only remaining abnormal pyramid called the blunted pyramid, for the reason that the inclination changes at about one-third of the height. This pyramid forms one of a group of four, two of stone, and, be it carefully borne in mind, two of brick; their dimensions are 700 × 700 × 326 feet; 620 × 620 × 321 feet; 350 × 350 × 90 feet; and 343 × 343 × 156 feet.

One of these pyramids was formerly supposed to have been built by Seneferu; if any of them had been erected by King Ousertsen III. of the twelfth dynasty, as was formerly thought, the hypothesis we are considering would have been invalid.

Only after Seneferu, then do we come to the normal Egyptian pyramid, the two largest at Gizeh built by Cheops and Chephren (fourth dynasty) being, so far as is accurately known, the oldest of the series. (According to Mariette the date of Mini is 5004 B.C., and the fourth dynasty commenced in 4235.)

Associated with the cities with east and west walls are temples facing due east, fit, therefore, to receive the rays of the morning sun rising at an equinox.

Associated with these pyramids carefully oriented east and west, we find on their eastern sides some distance away, and on a line passing through their centres at right angles to a meridian line, temples facing due west, the clearest possible indication of equinoctial worship. At sunset at the equinox the sepulchral chamber and the sun were in line from the adytum. The priest faced a double Osiris.

In the case of the pyramid of Chephren, not only have we, as I hold, such a temple of Osiris, but the Sphinx granite temple was most probably the crypt of a temple of Isis, its relation to the south face of the pyramid being borne in mind. If this were so Osiris was a name both for the solstitial and equinoctial sun.

Other pyramids were built at Sakkarah during the sixth dynasty, but it is remarkable that such a king as Pepi-Meri-Rā should not have imitated the majestic structures of the fourth dynasty. He is said to have built a pyramid at Sakkareh, but its obscurity is evidence that the pyramid idea was giving way, and it looks as if this dynasty were really on the side of On,[2] for the authority of Memphis declined, and Abydos was preferred, while abroad Sinai was reconquered, and Ethiopia was kept in order.[3]

The sphinx (oriented true east) must also be ascribed to the earliest pyramid builders; it could not have been built before their intrusion. The Colossi of the plain at

[1] Maspero, *op. cit.* p. 59. [2] Maspero, *op. cit.* p. 80.
[3] Further, it is known that there was some connection between Pepi-Meri-Rā and the eleventh dynasty of Thebes. Maspero, *op. cit.* p. 91.

Thebes was a subsequent reply of the On solstitial worship to it.

(b) The Worship of the Bull by the Pyramid Builders.

There is a subsidiary point in connection with the pyramid builders and equinoctial worship.

The worship of Apis preceded the building of pyramids. Mini is credited by Elian with its introduction,[1] but at any rate Kakau of the second dynasty issued proclamations regarding it,[2] and a statue of Hapi was in the temple of Cheops.[3]

It is stated that the first month of the Chaldæan year was dedicated to the "propitious bull," and that the figure of a bull constantly occurs on the monuments as opening the year. Now the sun *at the vernal equinox* 4500 B.C. was in the constellation Taurus. Biot has shown that the equinox occurred with the sun near the pleiades in 3285 B.C. We seem driven to the conclusion that the constellation of the bull dates from this time, and that Hapi represented it.[4]

(c) The Art of the Pyramid Builders.

Another connecting link is found in the diorite statues found in the temple of Chephren, at the pyramids, and at Tell-loh (ancient Sirgalla) by M. de Sarzec in 1881.

This last find consisted of some large statues of diorite, and the attitude chosen was that of Chephren himself as represented in the Museum of Gizeh.

This indicates equality in the arts and the possession of similar tools in Chaldæa and Egypt about the time in question.

(d) The Star Worship of the Pyramid Builders.

I have given before the gods of Heliopolis, and have shown that with the exception of Sit none are stellar; and that the temple of Sit is still represented. But we find in pyramid times the list is vastly changed; only the Sun gods Ra, Horus, Osiris, are common to the two. As new divinities we find[5]:—

Isis.
Hathor.
Nephthys.
Ptah.
Selkit.
Sokhit.

Of these the first two and the last two undoubtedly symbolised stars, and there can be no question that the temple of Isis at the pyramids was built to watch the rising of some of them.[6] Of Iris and Hathor I have already written at length, and I think the stars are now known. The others are more doubtful, but it may be that Ptah = Capella and Selkit = Antares.

But it is also stated that at Memphis[7] [time not given] there were temples dedicated to Soutekh and Baal. Now this is of great importance, for I suppose there is now no question among Egyptologists that the gods Set, Sit, Typhon, Bes, Soutekh, Soutkhou are identical. It is also equally well known that Soutekh was a god of the Canaanites[8] that the hippopotamus, the emblem of Set and Typhon, was the hieroglyph of the Babylonian god Baal,[9] and Bes is identified with Set in the book of the dead.[10]

[1] Maspero, *op. cit.* p. 44, note. [2] Maspero, *op. cit.* p. 46.
[3] Maspero, *op. cit.* p. 64.
[4] Not only the bull; there is evidence in favour of the view that the goddess Selk = Antares. If so, the scorpion constellation had also been established, and *both* equinoxes marked by constellations in the time of Cheops. [5] Maspero, *op. cit.* p. 64.
[6] The temple of Saïs, as I have said, had east and west walls, and so had Memphis, according to Lepsius. The form of Isis at Saïs was the goddess Neith, which, according to some authorities, was the precursor of Athene. The temple of Athene at Athens was oriented to the Pleiades.
[7] Maspero, *op. cit.* p. 357.
[8] Maspero, *op. cit.* p. 165. [9] Pierret, p. 4. [10] *Idem*, p. 48.

Jensen in his "Kosmologie der Babylonier," p. 16, points out that Bīl was the name for the pole of the equator. If this be the Baal referred to by Pierret, we get the most marvellous coincidence between the Egyptian and Babylonian star-worship and suggestion of a common origin among an astronomically-minded people.

This suggests that the founders of On and Memphis had a common origin, and the Memphitic intrusion took place after solar solstitial worship had been introduced at On. This worship could not have been brought into Egypt from any other country, bordering on Chaldæa, and its ultimate predominance is the origin of the myth of Horus slaying the hippopotamus. Nay, it may be also suggested that the predominance was brought about by men and ideas reaching On from the south, so that the myth had a single celestial and a double terrestrial side.

The Hawk God of Edfû, Harhouditi, had for servants a number of individuals called Masniou or Masnitiou = blacksmiths, just as the Hawk God of the Delta, Harsiisit, has for his entourage the Shosou Horou. Maspero in a most interesting paper[1] has recently called attention to some customs still extant among the castes of blacksmiths in Central Africa, which have suggested to him that the followers of the Edfû Horus may have come from that province.

He writes: "C'est du sud de l'Égypte que les forgerons sont remontés vers le nord, leur siège primitif était le sud de l'Égypte, la partie du pays qui a le plus des rapports avec les régions centrales de l'Afrique et leurs habitants."

Then after stating the present conditions of these workers in equatorial Africa, where they enjoy a high distinction, he concludes:—

"Je pense qu'on peut se représenter l'Horus d'Edfou comme étant au début, dans l'une de ses formes, le chef et le dieu d'une tribu d'ouvriers travaillant le métal, ou plutôt travaillant le fer. On ne saurait en effet se dissimuler qu'il y a une affinité réelle entre le fer et la personne d'Horus en certains mythes. Horus est la face céleste (horou), le ciel, le firmament, et ce firmament est de toute antiquité, un toit de fer, si bien que le fer en prit le nom de ba-ni-pit, métal du ciel, métal dont est formé le ciel: Horus l'aîné, Horus d'Edfou, est donc en réalité un dieu de fer. Il est, de plus, muni de la pique ou de la javeline à point de fer, et les dieux qui lui sont apparentés, Anhouri, Shou, sont de piquiers comme lui, au contraire des dieux du nord de l'Égypte, Ra, Phtah, etc., qui n'ont pas d'armes à l'ordinaire. La légende d'Harhouditi conquérant l'Égypte avec les masniou serait-elle donc l'écho ointain d'un fait qui se serait passé au temps antérieurs à l'histoire? Quelque chose comme l'arrivée des Espagnols au milieu des populations du Nouveau Monde, l'irruption en Égypte de tribus connaissant et employant le fer, ayant parmi elles une caste de forgerons et apportant le culte d'un dieu belliqueux qui aurait été un Horus ou se serait confondu avec l'Horus des premiers Egyptiens pour former Harhouditi. Ces tribus auraient été nécessairement d'origine Africaine et auraient apporté de nouveaux éléments Africains à ceux que renfermait déjà la civilisation du bas Nil. Les forgerons auraient perdu peu à peu leurs privilèges pour se fondre au reste de la population: à Edfou seulement et dans les villes où l'on pratiquait le culte de l'Horus d'Edfou, ils auraient conservé un caractère sacré et se seraient transformés en un sorte de domesticité religieuse, les masniou du mythe d'Horus, compagnons et serviteurs du dieu guerrier."

3.—The Work of the Eleventh and Twelfth Dynasties.

We have next to consider what happened after the great gap in Egyptian history between the sixth and twelfth dynasties, 3500 B.C.–2851 B.C. (Mariette), from

[1] *L'Anthropologie*, July-August, 1891, No. 4.

Nitocris to Amenemhat I. We pass to the Middle Empire.

Amenemhat I. built no pyramids, he added no embellishments to Memphis; but he took Heliopolis under his care, and now we first hear of Thebes.[1]

Usertsen I. built no pyramids, he added no embellishments to Memphis, but he also took Heliopolis under his care, and added obelisks to the temples, one of which remains to this day. Further, he restored the temple of Osiris at Abydos, and added to the temple of Amen-Rā at Thebes.[2]

Surely it is very noteworthy that the first thing the kings of the twelfth dynasty did was to look after the only three temples in Egypt of which traces exist, which I have shown to have been oriented to the solstice.

It is right, however, to remark that there seems to have been a mild recrudescence of pyramid building towards the end of the twelfth dynasty, and immediately preceding the Hyksos period, whether as a precursor of that period or not.

Usertsen's views about his last home have come down to us in a writing by his scribe Mirri:[3]—

"Mon maître m'envoya en mission pour lui préparer une grande demeure éternelle. Les couloirs et la chambre intérieure étaient en maçonnerie et renouvelaient les merveilles de construction des dieux. Il y eut en elle des colonnes, sculptées, belles comme le ciel, un bassin creusé qui communiquait avec le Nil, des portes, des obélisques, une façade en pierre de Rouou."

There was nothing pyramidal about this idea, but 150 years later we find Amenemhat III. returning both to the gigantic irrigation works and the pyramid building of the earlier dynasties.

The scene of these labours was the Fayyûm, where, to crown the new work, two ornamental pyramids were built, surmounted by statues, and finally the king himself was buried in a pyramid near the Labyrinth.

4.—*The Work of the Eighteenth Dynasty.*

The blank in Egyptian history between the twelfth and eighteenth dynasties is known to have been associated with the intrusion of the so-called Hyksos. It is supposed these made their way into Egypt from the countries in and to the west of Mesopotamia. It is known that they settled in the cities with east and west walls. They were finally driven out by Aahmes, the king of solstitial solar Thebes, who began the eighteenth dynasty.

In (*a*) I have shown what happened after the first great break in Egyptian history—a resuscitation of the solstitial worship at On, Abydos and Thebes.

I have next to show that precisely the same thing happened after the Hyksos period (Dyn. 13 (?), Mariette, 2233 Brugsch; Dyn. 18, 1703 B.C., Mariette) had disturbed history for some 500 years.

It is known from the papyrus Sellier (G.C. 257) that Aāhmes, the first king of the eighteenth dynasty, who re-established the independence of Egypt, was in reality fighting the priests of Soutekh in favour of the priests of Amen-Rā, the solstitial solar god, a modern representative of Atmu of On.

Amen-Rā was the successor of Menthu, the successor of Atmu of On. So close was the new worship to the oldest at On, that at the highest point of Theban power the third priest of Amen took the same titles as the Grand Priest of On, "who was the head of the first priesthood in Egypt."[4] The "Grand Priest of On," who was also called the "Great Observer of Rā and Atmu," had the privilege of entering at all times into the *Habenben* or Naos. The priest Padouamen, whose mummy was found in 1891, bore these among his other titles.

[1] Maspero, *op. cit.*, p. 112. [2] Maspero, *op. cit.* p. 112.
[3] Maspero, *op. cit.* p. 113. [4] Virey, New Gizeh Catalogue, p. 263.

The assumption of the title was not only to associate the Theban priesthood with their northern *confrères*, but surely to proclaim that the old On worship was completely restored.

5.—*The Work of the Twenty-fifth Dynasty.*

There was another invasion from Syria, which founded the twenty-second dynasty, and again the government is carried on in cities with east and west walls (Sais, Tanis, and Bubastis). The solstitial solar priests of Thebes withdraw to Ethiopia. They return, however in 700 B.C., drive out the Syrian invaders, and, under Shabaka and Taharga, found a dynasty (the twenty-fifth) at Thebes, and embellish the solstitial solar temples there.

6.—*Anthropological Evidence.*

It will be seen then that a general survey of Egyptian history does suggest conflict between two races, and this of course goes to strengthen the view that the temple building phenomena suggest two different worships, depending upon race distinctions.

We have next to ask if there is any anthropological evidence at our disposal. It so happens that Virchow has directed his attention to this very point.[1]

Premising that a strong race distinction is recognised between peoples having brachycephalic or short, and dolicocephalic or long, skulls, and that the African races belong to the latter group, I may give the following extract from his paper:—

"The craniological type in the Ancient Empire was different from that in the middle and new. The skulls from the Ancient Empire are brachycephalic, those from the new and of the present day are either dolichocephalic or mesaticephalic; the difference is therefore at least as great as that between the dolichocephalic skulls of the Frankish graves and the predominantly brachycephalic skulls of the present population of South Germany. I do not deny that we have hitherto had at our disposal only a very limited number of skulls from the Ancient Empire, which have been certainly determined; that therefore the question whether the brachycephalic skull-type deduced from these was the general or at least the predominant one cannot yet be answered with certainty, but I may appeal to the fact that the sculptors of the Ancient Empire made the brachycephalic type the basis of their works of art too."

It will be seen, then, that the anthropological as well as the historical evidence runs on all fours with the results to be obtained from such a study of the old astronomy as the temples afford us.

J. Norman Lockyer.

NOTES.

On Monday, May 29, the Duke of Connaught will open the new engineering and electrical laboratories at University College, London.

A general meeting of the members of the Federated Institution of Mining Engineers will be held in the rooms of the Institution of Civil Engineers, 25, Great George Street, Westminster, on Thursday, June 1, at 12 noon, and on Friday, June 2, at 10 a.m.

The Niederrheinische Gesellschaft für Natur- und Heilkunden at Bonn, proposes to celebrate its seventy-fifth anniversary on July 2. A scientific meeting will be held in the forenoon in the music hall of the University of Bonn, and at one o'clock the members will dine together at the hotel "Zum Goldenen Stern." In the afternoon there will be an excursion to Rüngsdorf.

[1] Prof. R. Virchow: "Land und Leute im alten und neuen Aegypten." *Verhandlungen der Gesellschaft für Erdkunde zu Berlin*, pp. 434-436, Band xv. No. 9.

CAPTAIN E. C. HORE, who was for many years in command of the mission steamer on Lake Tanganyika, and received in 1890 one of the Royal Geographical Society's awards for his observations on the physical geography of the lake, has arranged an interesting little exhibition at 48, Pall Mall, which will be formally opened tomorrow, May 19, at 4 p.m., when a number of distinguished African explorers and administrators will be present. The exhibition contains a number of African curios collected by Captain Hore, and models illustrating native life and industries in a very realistic manner. It will only be open for a few weeks, and is well worthy of a visit from all interested in the geography or in the future development of the region marked out by Nature as the future highway through the continent of Africa.

THE annual dinner of the Royal Geographical Society was held at the Whitehall Rooms, Hôtel Métropole, on Saturday, Sir M. E. Grant Duff in the chair. Among the toasts of the evening was that of "The Medallists Designate." In proposing this, the Chairman explained that the dinner usually took place on the evening of the anniversary meeting, but the rooms could not be obtained for that day, and therefore the medals had not yet been conferred. All would agree that the choice of the council had fallen upon very worthy recipients. The first was Mr. Selous, whom they welcomed that evening. The second medallist designate was Mr. Woodville Rockhill, an American diplomatist, who had made himself famous by his explorations in Western China and North-eastern Tibet. Mr. Selous, in responding, said that at a very early period of his African travels he had made sketch maps, and he had never ceased to do so in all the countries through which he had travelled. He had been able to make a pretty correct survey of Mashonaland, and he looked with the most intense pride and satisfaction to the fact that he had seen a British colony spring up in that country, which he was one of the first to explore. Lord Kelvin responded for "The Allied Sciences," proposed by Mr. Seebohm. Mr. W. T. Thiselton Dyer proposed "The Royal Geographical Society." The Chairman, in replying, said he looked back with pleasure upon the almost unclouded prosperity which the Society had enjoyed for the four years during which he had been President. Their numbers this year had sprung forward again, and their total number was close upon 3700.

THE *Botanisches Centralblatt* has published a full description of the newly established Biological Institute at Heligoland, which is now at full work. The Director is Prof. Heincke, with Dr. Hartlaub as assistant for zoology, and Dr. Ehrenbaum for the high-sea fisheries, while Dr. P. Kuckuck superintends the botanical investigations. Donations to the library are especially asked for.

M. DUCHARTRE has been elected President of the Botanical Society of France for the current year, with MM. Guignard, Clos, Poisson, and Zeiller as Vice-presidents.

THE greater part of the Kew Bulletin for February and March, which has just been issued, consists of an account of the known habits and the economic treatment of the insect commonly known as the palm weevil, which during the last five or six years has been doing enormous injury to the industry of cocoa-nut palm growing in British Honduras. The paper cannot fail to be of service to planters engaged in this industry. The number contains also, besides miscellaneous notes, the fifth decade of new orchids.

THE London Botanical Field Class, which was established in 1891, will make seven field excursions during the present summer, the first of them taking place on May 27. The director is Prof. G. S. Boulger.

DURING the past week the day temperatures have generally been considerably above the average for the season, the readings at some of the central and southern stations exceeded 70°, and reached from 75° to 80° over our south-eastern and south-midland counties; but in some parts of the north and north-west the daily maxima have not reached 60°. During the first part of the period barometric depressions approached the north of Scotland and spread southwards, bringing light rains to the northern and western parts of the country; but the fall was below the average amount, while in the south and east of England no rain fell until the 15th inst. The long drought, which in many places was brought to a close on Monday by the advance of a subsidiary depression over the southern portion of the kingdom, had lasted in parts of Kent and Hampshire for fifty-eight days, during which time absolutely no rain fell there. Towards the close of the period the type of weather became very unsettled, and thunderstorms occurred in many parts, accompanied by rain or hail, but, with few exceptions, the fall up to Tuesday, the 16th inst., was not heavy. The *Weekly Weather Report* of the 13th inst. showed that the amount of bright sunshine was much above the average. In London it was 76 per cent. of the possible amount, which is higher than any percentage previously recorded in the metropolis since sunshine instruments were established in 1880. In the Channel Islands the percentage was as high as 88, and over England generally it ranged from 60 to 78 per cent.

THE report of the Kew Committee for the year 1892, the publication of which was noted in our last issue, states that the principal magnetic disturbances were recorded on February 13 and 14, March 6 and 12, April 26, May 18, July 16 and 17, and August 12. The most marked disturbance was that which commenced on February 13; the oscillations were of a more extended and violent character than any which have been recorded during the last ten years. The tabulations of the meteorological traces and other observations have been transmitted to the Meteorological Office, and detailed information of all thunderstorms has been forwarded to the Royal Meteorological Society. Sketches of sun-spots were made on 178 days; on no occasion during the year, when observations have been taken, has the sun's surface been found free from spots, and the number of new groups enumerated has largely increased. The number of instruments verified during the year was nearly 21,000, the great majority being clinical thermometers, and, in addition, a large number of watches have been examined.

THE Meteorological Council have just issued a summary of rainfall and mean temperature for the first quarter of the twenty-eight years 1866 to 1893, based upon the observations published in the *Weekly Weather Report*. The figures show some interesting details of the weather in each of the twelve districts into which the country is divided for the purpose of weather forecasts. In every district except the north of Scotland and the east of England there was a deficiency in the amount of rainfall. In the principal wheat-producing districts the greatest deficiency was in the Midland Counties, being 1·1 inch, and the east of Scotland 1·3 inch, while in the principal grazing, &c., districts the deficiency was still larger, being 2·0 inches in the south-west of England, and 2·7 inches in the north-west of England. The deficiency for the whole of the British Islands (omitting the Channel Islands and the North of Scotland) was 1·3 inch. The temperature in every district exceeded the mean, except the north of Scotland, where it just equalled it. The largest excess was 1°·3 in the north of Ireland, and 1°·2 in the north-east of England. The excess for the British Islands generally was 0°·8; the mean temperature for the last quarter, notwithstanding the severe cold experienced at the beginning of the year having been only just exceeded once in the last nine years.

THE first part of Prof. Newton's "Dictionary of Birds" which has long been announced as in preparation will be published next month. It is based upon the articles contributed by him to the ninth edition of the "Encyclopædia Britannica," but contains large numbers of others by himself and Dr. Gadow, the Strickland Curator at Cambridge, together with contributions by Mr. Lydekker, Prof. Roy, and Dr. Shufeldt. The work is to consist of four parts, and when complete will form a demy 8vo volume of about 1000 pages, copiously illustrated, and the publishers Messrs. Adam and Charles Black, promise the second part in October next.

IN the current number of the American *Journal of Science* Mr. Pupin gives the second part of his paper on electrical oscillations of low frequency and their resonance (see NATURE, April 20, 1893). This portion consists chiefly of a theoretical investigation of the rise of potential in a circuit which is in resonance with a periodical impressed electromotive force. This rise was shown in a very striking manner by connecting two large choking coils and a condenser in series with the secondary of a transformer, a Thomson electrostatic voltmetre being connected to the terminals of the condenser, and the core of one of the choking coils consisting of a movable bundle of solf iron wires. The frequency of the impressed electromotive force being about 100 per second, the capacity of the condenser was adjusted until the removal of the plug was accompanied by bright sparks, showing that resonance was near. Then the movable iron core was adjusted till the voltmetre gave the longest deflection obtainable. In this way a rise from 60 volts (generated in the secondary and indicated by a Cardew voltmetre) to about 900 volts was easily obtained. The rise of potential is practically confined to the condenser, there being, however, a large and rapid increase in the current on the approach of resonance, which increase can be studied in a rough way by the pull which the choking coil exerts on the movable iron core when this is being adjusted to give resonance.

THE question as to the cause of earth currents is one of considerable interest, and has not yet been satisfactorily answered. A paper read before the Institute of Electrical Engineers by Mr. O. E. Walker, giving a further account of his observations made in India seems to show, however, a clear connection between the variations in the earth currents and those of the atmospheric pressure. On account of the long periods of settled weather experienced in India, that country is particularly well suited for the investigation of any such relation. Observations were made on four lines, and show, in almost every case, that in the morning the current flows from the inland place of observation to the coast, while in the afternoon the direction is reversed. The maximum current in one direction occurs at 10 a.m. local time, this also being the time of the morning maximum reading of the barometer, while the maximum current in the opposite direction occurs at 3 p.m., the time of the afternoon minimum of the barometer. Another point of interest is that the maxima of the earth currents occur when the diurnal variation of the declination is zero.

ON a clear, cold, winter afternoon, about half an hour before sunset, a peculiar phenomenon of refraction of light can be witnessed on a fresh field of snow, which is described by Mr. Albert W. Whitney in the *American Journal of Science*. Two roughly V-shaped paths, of especial, though not exclusive brilliancy, open away from the observer and towards the sun. The apex of one is perhaps six feet away, its angle 90°; the apex of the other is perhaps fifteen feet away, its angle 60°. The light is not diffused, but made up of many separate brilliant points, glowing with prismatic colours. The paths are broad, several degrees in width, their inner margin being more sharply defined than their outer limit. Measurements with a sextant have shown that all the glowing points lie in the surfaces of two cones, whose axes pass through the sun and the eye of the observer, and whose angles are approximately 22° and 46°. Hence the paths are hyperbolas, and their visibility depends upon the altitude of the sun above the horizon. Mr. Whitney explains the phenomenon as analogous to that of halos. It is largely, perhaps mostly, due to frost crystals. They form more slowly, hence more regularly, than snow crystals. The fact that snow hyperbolas are usually more conspicuous in the late afternoon than in the early morning, may be explained by the frost crystals needing a certain amount of clearing up by sun and wind of minute secondary accumulations of frost upon themselves, to make them fit for transmitting light. Another interesting fact concerns the relation of the other limb of the hyperbola to that upon the snow. If the observer walks so as always to keep one certain point in the path of light, his track will be an hyperbola; if now, from the apex of the hyperbola which he has traced, he advances a distance equal to his height multiplied by the cotangent of the altitude of the sun plus half the vertical angle of the cone, the figure which he now sees and the figure which he has traced upon the snow are the two limbs of the same hyperbola.

THE determination of the refractive index of the atmosphere has until recently been confined to the visible spectrum. Messrs. Kayser and Runge, in a communication to the Berlin Academy, describe a method of obtaining it for every portion of the photographic spectrum. If a prism is introduced between a Rowland concave grating and the sensitive plate, the rays are deflected, and the spectrum appears displaced on the plate. From the amount of this displacement and the distance of the prism from the plate it is easy to deduce the angle of deflection of the rays in question, and the refractive index of the prism. The prism used was hollow, made of copper and closed by quartz plates. The prism was filled with air under a pressure of about ten atmospheres Since the investigations of Mascart, Benoit, and Chappuis and Rivière have shown that the index of deviation of gases varies as the density, the refractive indices for air at zero and atmospheric pressure could be calculated from the results. Measurements were taken at seven different places along the spectrum, between wave lengths 563 and 236$\mu\mu$. The refractive indices for some of the Fraunhofer lines thus obtained are the following:—

A	1·0002902
D	1·0002919
F	1·0002940
G	1·0002959
H	1·0002975
N	1·0003000
$\lambda = 236\mu\mu$	1·0003217

These values are for air under normal temperature and pressure but not for dry air. To correct for moisture the last decimal place must be increased by 3, thus giving for D, for instance, the value 1·0002922. In the hands of previous workers, the last two figures have varied between 11 (Lorenz) and 47 (Ketteler).

NO fewer than six volumes containing French translations of writings by Mr. T. H. Huxley are now included in the "Bibliothèque Scientifique Contemporaine," issued by J. B. Baillière et Fils. The latest of these six volumes is a series of essays, entitled "Science et Religion."

A volume embodying the meteorological results deduced from observations taken at the Liverpool Observatory during the years 1889-90-91 has been published by order of the Mersey Docks and Harbour Board.

THE atomic refraction of nitrogen, in the free state as gas and in the various types of nitrogen compounds, forms the subject of a communication to the *Berichte* by Prof. Brühl, of Heidelberg. The refractive power of free gaseous nitrogen has been determined with the highest attainable accuracy by Biot and Arago, Dulong, and other later observers, and the value of the atomic refraction, calculated from the mean of all these determinations, is 2·21. As the simplest type of nitrogen compound ammonia gas is next considered, in which the three affinities of the nitrogen are attached by single linkage to the three hydrogen atoms. The molecular refraction of ammonia calculated from its refractive index is 5·65. Now, if it is admitted that the hydrogen in this simple compound possesses the same atomic refraction (1·05 for sodium light) as in the free state and in other ordinary combinations, an admission in support of which Prof. Brühl has previously adduced a considerable amount of experimental evidence, then the atomic refraction of the nitrogen in ammonia is 2·50. The compounds of nitrogen with oxygen are next discussed. The atomic refraction of oxygen for sodium light is 2·05, the molecular refraction of the free gas O_2 being 4·09. If one calculates the molecular refraction of nitric oxide, NO, by adding together the atomic refractions of the gaseous elements 2·21 and 2·05, the number 4·26 is obtained. It is interesting to find that the molecular refraction of nitric oxide, calculated from the values obtained experimentally by Dulong and by Mascart for the refractive index of the gas, is very nearly the same, 4·47. Hence in nitric oxide both elements retain about the same refractive power as in the free state. The case of nitrous oxide, N_2O, however, is quite different and leads to an interesting conclusion. Its molecular refraction calculated from the observed refractive index of the gas is 7·58. The value, however, obtained by summation of the values of its components, 2 × 2·21 and 2·05, is only 6·47. The very considerable increase of 1·11 is due to the fact that we are here dealing with a case of double linkage, , the two nitrogen atoms being mutually attached by two of their affinities. Indeed the increase is probably more than this, for the atomic refraction of oxygen in organic compounds of this type has been found by Prof. Brühl to be less than the value above ascribed to it. The atomic refraction of the nitrogen in N_2O is therefore at least 2·77. It is thus found that nitrogen as singly linked in ammonia possesses an atomic refraction of 2·50, when doubly linked, as in nitrous oxide, 2·77, and when trebly linked, as it probably is in the free gas, 2·21. The value therefore increases with double linkage, but curiously enough diminishes again with treble linkage, unlike that of carbon, which still further increases with treble linkage, and showing that there is some very essential difference between the nature of the two elements. Prof. Brühl concludes his interesting paper by discussing the various values of nitrogen when combined with carbon. When it is attached with only one of its valencies to a carbon atom, as in the tertiary amines, its atomic refraction is found to be 2·90, a very high value, higher than that of the diazo nitrogen in nitrous oxide. When doubly linked to carbon, C : N, as in the oxims, there is a much larger increase still, the exact amount of which Prof. Brühl prefers to state after carrying out further determinations on a larger number of compounds. In case of cyanogen gas, N ⋮ C · C ⋮ N, where triple linkage of nitrogen occurs, there is also a very considerable increment (1·52) in refraction. In the case of hydrocyanic acid, however, the molecular refraction corresponds almost exactly with that calculated from the empirical formula HCN, showing that the cyanogen in this compound and in cyanogen gas are quite different in molecular structure, a point which Prof. Brühl hopes further to elucidate by observations of the refraction of the nitriles and other allied organic nitrogen compounds.

Erratum.—In our chemical note of last week (p. 39) $SObl_2$ and Hbl should read $SOCl_2$ and HCl.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include the Anthozoa *Gorgonia verrucosa* and *Caryophyllia Smithii*, the Nemertine *Drepanophorus rubrostriatus*, the Mollusca *Sepia rupellaria* (= *biserialis*), *Galvina tricolor* and *Antiopa cristata*, and the Ascidians *Corella larvæformis* and *Fragarium elegans*. Several swarms of the medusa *Obelia lucifera*, full-grown and mature, were taken in the townets during the latter half of the week. Polychæte larvæ, so abundant earlier in the year, are now very scarce. Zoææ of *Porcellana*, on the other hand, have increased in numbers, and every townetting contains a variety of Decapod larvæ in different stages of development. The Hydroids *Eudendrium capillare* and *Antennularia antennina*, and the Polychæte *Sabellaria spinulosa* are now breeding.

THE additions to the Zoological Society's Gardens during the past week include two Red-winged Parrakeets (*Aprosmictus erythropterus*, ♀ ♀) from Australia, presented by Mr. H. Goodchild; two Ravens (*Corvus corax*) British, presented by Mr. Philip A. Wilkins; a Ducorp's Cockatoo (*Cacatua ducorpsi*) from the Solomon Islands, presented by Mr. R. Armitage; a Changeable Lizard (*Calotes versicolor*) from Ceylon, presented by Mr. H. L. Gibbs; a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, a Common Peafowl (*Pavo cristatus*, ♂) from India, deposited; a Yellow-cheeked Lemur (*Lemur xanthomystox*) from Madagascar, eleven Green Lizards (*Lacerta viridis*) South European, purchased; a Senegal Touracon (*Corythaix persa*) from West Africa, received in exchange; a Japanese Deer (*Cervus sika*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE GREATEST BRILLIANCY OF VENUS.—Dr. G. Müller, whose work on the brightness of the major and some of the minor planets we referred to in this column two weeks ago (p. 15) contributes to *Astronomischen Nachrichten*, No. 3162, some interesting results with reference to the greatest brilliancy of Venus. That this planet does not appear brightest at the time of conjunction, but some days before or after, has been shown by the work of Halley, Lambert, &c., and the values, as obtained from their formulæ, are:—

Formula used.	The greatest brilliancy occurs at Angle of phase.	Elongation.	No. of days before or after inf. conj.	Greatest brilliancy.
	° ′	° ′		
Halley	117 56	39 43	36	4·263
Lambert	103 46	44 38	51	2·126
Bremiker	115 15	40 52	39	2·772
Seeliger	116 0	40 33	38	3·018

Referring to the curves of the observed and computed brightnesses, as here set forward by Dr. Müller, several important points may be noticed. In the former the maximum brightness takes place at a phase angle of 119°, decreasing very gradually to 140°, and after that more rapidly. At the maximum the curve is moderately flat, only a very small variation being noticed between position angle 100° and 140°, a period of 36 days.

Dr. Müller remarks that the statements of epochs given in the astronomical ephemerides have no practical interest. As an example showing the deviations of the values therein stated from those computed by his formula he works out the next epoch of the greatest brilliancy of Venus, which will be in inferior conjunction on February 15, 1894. The values for the brightness and the corresponding times result as follows:—

Jan. 9	oh. G.M.T.	$h = -4·3776$
10	,, ,,	−4·3798
11	,, ,,	−4·3809
12	,, ,,	−4·3809
13	,, ,,	−4·3802
14	,, ,,	−4·3782

which give for the epoch of greatest brilliancy January 11, 15h. M.T.G. The times of epoch, as given by the ephemerides, are:—

Berliner Ast. Jahrbuch	Jan. 8	16h. M.T.G.
Nautical Almanac	11	2h. ,,
Connaissance des Temps	12	1h. ,,

FINLAY'S PERIODIC COMET.—This comet, which was discovered by Finlay in 1886, is one, if not the only one, of the periodic comets due this year. The following is a search ephemeris for the present month for intervals of four days:—

1893.	R.A. h. m. s.	Decl. ° ′
May 20	23 48 12	−4 24
24	0 5 24	−2 34
28	0 22 57	−0 40
June 1	0 40 53	+1 16

L'Astronomie FOR MAY.—This number commences with the discourses delivered by M. Tisserand and M. Flammarion before the Astronomical Society of France, the former "On the Progress of Astronomy during the Past Year," and the latter "On the Progress of the Society itself.—A brief but interesting article from the pen of Dr. Lorin, on "Celestial Photography," will be of special value to possessors of small instruments, since he shows how they can be adapted for the taking of such photographs. With reference to the late solar eclipse, several observatories have communicated their observations as made on the Continent, accompanying them with drawings, which are here inserted.

THE LUNAR ATMOSPHERE.—At the Observatory of Alger, M. Spée (*Comptes Rendus*, April 24, No. 17) made some interesting observations to find out whether any modifications due to a lunar atmosphere were produced in the lines of the solar spectrum (1) in the neighbourhood of the horns, and (2) at the point of contact of the lunar disc with a sun-spot. The observations, he says, were made under the best conditions, but gave a negative answer to the first of these two investigations. With regard to the second he says that no change was noted until at the moment of the greatest phase when the lines of magnesium b^1 b^2 b^4 "appeared sharp and seemed to be accompanied on both sides with very fine lines reminding one of what in spectroscopy is known under the name of *persiennes*. C was terminated, as M. Spée says, "*en fer de lance*" penetrating the chromosphere.

BULLETIN ASTRONOMIQUE FOR APRIL.—In this periodical for the past month M. Haerdtl contributes some notes relative to some small inequalities of long period in the movements of the Moon, Earth, and Mars. The determination of the orbit of the periodical comet Finlay (1886 vii.) is the subject of a long article by M. Schulhof, but in this (to be continued in the next) he only limits himself to the ephemeris and the mean positions of the comparison stars, with copious notes giving the authorities, proper movements, and remarks. *Apropos* of the question of the variation of latitudes M. Boquet gives an interesting historical notice on the latitude of the Observatory of Paris, in which he recapitulates all the attempts made to fix the value of this important element. Now that we know that variations occur, it is most interesting to read the remarks of the authors of these various determinations at different times with respect to the discrepancies between the values. M. Yvon Villarceau for instance, from his observations in 1866 and 1867 says: "Quant à la mesure exacte de la latitude, nous ne voyons pas qu'elle puisse résulter des mesures faites aux Cercles muraux de Gambey et de Fordin." . . . .

GEOGRAPHICAL NOTES.

THE death of Mr. W. Cotton Oswell on May 1st, at the age of 75, removed a famous African traveller and hunter whose name had almost ceased to be remembered by the general public. In his early life Mr. Oswell spent five years in South Africa hunting and exploring. His adventures were of the most thrilling kind, and the trophies he preserved in his house at Groombridge form a unique collection. He was associated with Livingstone in his earlier travels, and charged himself with the care of the waggons and the provision of food, while his companion planned the route and made scientific observations. In this way Mr. Oswell was with Livingstone at the discovery of Lake Ngami. Subsequently Mr. Oswell travelled and made collections in South America and elsewhere, but his extreme modesty prevented him from thrusting himself before the public, and he wrote nothing. His geniality in private life was as remarkable a feature of his character as his shrinking from all public appearances.

THE Canadian Government has decided to despatch an expedition, under the charge of Mr. J. B. Tyrrell, of the Geological Survey of Canada, to explore the barren ground northward from Lake Athabasca, a region which has not been visited by competent observers since 1772.

M. MARCEL DUBOIS has been appointed to the Chair of Colonial Geography, the foundation of which at the Sorbonne we intimated last year.

THE higher teaching of geography in England is not confined to the lectures delivered at the two ancient Universities. For some years Prof. C. Lapworth, F.R.S., has given courses on physical and political geography at the Mason College, Birmingham, which are this session attended by over eighty students. The complete course occupies two years, lectures being given twice a week; the syllabus is drawn out on thoroughly scientific lines, and while entirely original in treatment is comparable with the best instruction given in the same subject in German Universities.

ENGINEERING works of such magnitude as to be of geographical importance have been for some time carried out on the Alsatian slope of the Vosges in order to regulate the water supply for industrial purposes. A series of reservoirs, so large as to be described as artificial lakes, has thus been formed, and the rainfall of the district can now be utilised much more completely than was formerly possible.

THE FUNDAMENTAL AXIOMS OF DYNAMICS.

IN view of a discussion at the Physical Society of London on Friday, the 26th inst., it may be convenient if I anticipate future communications so far as to give in a brief or summary form the "Laws of Motion" somewhat as I propose to advocate their acceptance; not, however, entering into details, and not being specially careful about precise form of words, rather aiming at giving the general sense with the object of assisting discussion by abbreviating or summarising my paper in a few definite statements.

Notions derived more or less directly from sensations, and here accepted as understood without special definition.

Motion, Space (extent and direction), Velocity (including direction), Time, Stress, Force (including direction), Matter.

About all these there is much to say; some are more immediate sense-perceptions than others, but a detailed discussion of them verges on metaphysics, and is not an *essential* preliminary to a physical treatise. All that is *necessary* is explanation and illustration sufficient to render the terms intelligible. All that I shall say here is that by "matter" is meant primarily something tangible or resisting; that we experience "force" when we push a truck; that a thumbscrew gives us a notion of "stress": and that pushing a truck does also, if we attend to both hands and feet.

Remarks, Practical Assumptions, and Experiments.

There is no need to discriminate a force from a vector in a fundamental treatment, because all ideas about moment of force, angular momentum, and the like, belong to a consideration of the behaviour of a rigid body, which is an artificial agglomeration of connected particles: convenient, not fundamental.

But there are some assumptions and experiments needful to be made concerning the measurement of force more precisely than by our muscles.

(*Assumption* 1). That the weight of a given piece of matter at a given place is not liable to capricious change.

(*Assumption* 2). That two similar lumps of matter weigh twice as much as either.

(*Experimental result* 1). That strains of elastic bodies are proportional to the stresses within certain limits.

(*Experimental result* 2). That the frequency of a loaded elastic body, vibrating within the above limits is independent of amplitude.

(*Experimental result* 3). That in cases of impact there is one point whose motion is undisturbed by the blow.

Definitions, Simple Experiences, and Axioms.

(*Experience* 1). A stress consists of two forces.

(*Definition* 1). Acceleration (including direction) = dv/dt.

(*Experience* 2). Acceleration occurs in matter subject to an unbalanced force.

(*Axiom* 1). Without force there can be no acceleration of matter.

(*Experience* 3). The acceleration appears to agree with the force in direction, and is in some cases demonstrably proportional to the force. (A deduction from experimental result 2 above.)

(*Axiom* 2). The acceleration of a given piece of matter is proportional to the (effective or resultant or unbalanced) force acting on it, and is in the same direction.

(*Experience* 4). Stresses in a body do not accelerate it as a whole.

(*Axiom* 3). The two forces of a stress are always balanced.

[*Or otherwise* (after Experience 3).]

(*Definition* 2). The ratio of the force acting to the acceleration produced in a given piece of matter is called its "inertia."

(*Axiom a*). The inertia of a given piece of matter is unconditionally constant, and has no direction.

(*Remark*). Inertia is therefore taken as the most fundamental property of matter, and is used to measure its massiveness or "mass."

(*Definition* 3). The centre of mass of a system is a point such that $\Sigma(mr) = 0$; *or*, it is a point moving with speed v, such that $\Sigma(m)\mathrm{v} = \Sigma(m\mathrm{v})$.

(*Axiom b*). The centre of mass of a system is not accelerated by internal stresses, but only by one component of a stress whose other component acts on a body foreign to the system.

(*Deduction*). The two forces of a stress are always equal and opposite.

(*Remark*). A brief and convenient statement of Axiom 2, by help of Definitions 1 and 2, is $\mathrm{F}dt = m d\mathrm{v}$. Note that F and dv have necessarily the same sign; they are parallel vectors.

(*Experience* 5). Every force is one component of a stress; in other words, bodies can only mechanically act on one another (*i.e.* so as to affect each other's motion) by means of stress; or stress is essential to mechanical action.

(*Remark*). This might have been made part of Axiom 3, but it is really a distinct statement. Perhaps it should be stated as an axiom.

(*Axiom* 4). A stress cannot exist in or across empty space.

(*Deduction*). Therefore bodies (or any media) immediately acting on each other are necessarily in contact, and stress exists at the point of contact, where the normal components of their velocities (v) are identical.

(*Experience* 6). When stress and motion coexist, action occurs or activity is manifested.

(*Definition* 4). The scalar product of the two vectors Fv is called "activity."

(*Deduction*). The activities of two immediately acting bodies are equal and opposite.

(*Remark*). Elastic bodies under stress, and moving bodies with inertia, are found to be able to manifest activity, and are said to possess energy whereby they can do work on other bodies. Stress energy is called potential; motion energy is called kinetic.

(*Definition* 5). Work done $= \int(\text{activity})dt =$ energy gained or lost.

(*Remark*). There are two ways of regarding this quantity: $\int \mathrm{F}v dt$; namely either as $\mathrm{F}(vdt) = \mathrm{F}ds =$ change of potential energy, or as $v(\mathrm{F}dt) = v.m d\mathrm{v} =$ change of kinetic energy.

A body for which Fv is positive is losing energy; a body for which Fv is negative is gaining energy.

(*Deduction*). Since the activities of two immediately acting bodies are equal and opposite it follows by Definition 5 that energy lost by one is gained by the other; *i.e.*, that energy is simply transferred without loss or gain across the point of contact in the direction of the common velocity.

(*Axiom* 5). Energy which is not being actively transferred from one body to another remains unaltered in quantity and form.

(*Remark*). Energy which is being transferred from one body to another changes its form. The kind of transformation depends on the sign of dv with respect to the common velocity of the acting bodies at their point of contact.

If vdv is positive, energy is being transformed into kinetic; if vdv is negative, it is being transformed into potential; if vdv is zero, there is a mere flux or transmission of energy without transformation.

(*Deduction*). Since transference of energy is essential to activity it follows that only bodies which are able automatically to part with some of their energy, are able automatically to do work. In other words, automatically transferable energy is alone available or potential.

(*Experience* 7). The automatically transferable or potential energy of a body or system is liable to transfer and transform itself into kinetic. Hence

(*Axiom* 6). The potential energy of a system tends towards zero.

(*Experience*). Kinetic energy is only available when associated with appreciable or relative momentum.

The following statements may be made about the irregular and aggregate motion of particles called Heat.

(*Experience*). Heat will not flow from low to high temperature by mere conduction (as it could, for a time, if it possessed inertia, like water, air, or electricity). It can only flow from cold to hot by help of convection by matter or something else. Such flow is therefore not a cyclical or perennial process.

(*Deduction*). Energy of average temperature is useless for continuous work. In other words, the only available or potential portion of heat-energy, when dealt with in the aggregate, is that which a body is able freely to emit to colder bodies.

(*Definition*). The absolute temperature of a body is to its total heat-energy as the available fall of temperature is to its potential heat-energy.

OLIVER LODGE.

THE ROYAL SOCIETY SOIRÉE.

THE Royal Society Soirée on May 10 was in every way most successful. It was very numerously attended, and much interest was excited by many of the exhibits and by the demonstrations. In the following account of the exhibits we give a full account only of such objects as have not before been referred to in NATURE:—

Captain Abney, C.B., F.R.S., and General Festing, F.R.S., exhibited experiments on the extinction of light and colour.

Sir J. B. Lawes, Bart., F.R.S., and Dr. J. H. Gilbert, F.R.S., exhibited a series of photographs relating to the working of the Rothamsted Laboratory. In experiments on the growth of root-crops year after year on the same land, it was found that after a very few years of growth without manure, the root no longer developed the swollen character of the cultivated plant, but remain fusiform as in the uncultivated condition. The photographs strikingly show the same characters in roots grown in rotation without manure; also that mineral manures alone greatly favour the development of the swollen root, but that mineral and nitrogenous manures together do so in a much greater degree. The results further show how artificial a product is the cultivated root-crop, and how dependent it is on an abundant supply of food within the soil—nitrogenous as well as mineral. Indeed, details of the experiments afford conclusive evidence that it is quite fallacious to suppose that root-crops derive a large amount of their nitrogen from atmospheric sources by means of their extended leaf surface.

Three instruments for the study of Crystals were shown by Mr. H. A. Miers. (1) A goniometer by which crystals can be measured under liquids, or during their growth from solution. (2) A stage-goniometer by which small crystals or fragments can be adjusted and rotated under the microscope. It is here fitted to the stage of the petrological microscope designed by Mr. A. Dick. (3) An improved form of polariscope on the plan devised by Prof. W. G. Adams, F.R.S. The hemispheres which enclose the crystal section can in this instrument be accurately centred so that exact measurement of the optic axial angle is possible.

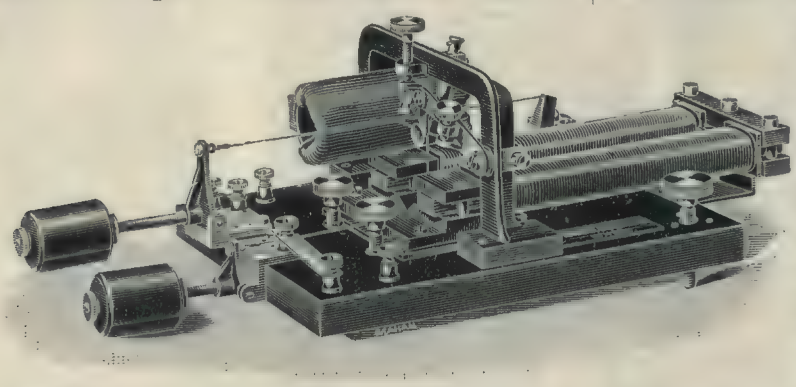
Prof. Rücker, F.R.S., and Prof. Thorpe, F.R.S., exhibited maps showing the forms of the true lines of equal declination, equal horizontal force, and equal dip in the United Kingdom for the epoch, Jan. 1, 1891.

Mr. A. A. C. Swinton exhibited high frequency electric experiments. (1) The filament of an ordinary 5 c.p. 100-volt lamp is caused to incandesce with current conveyed through the human body. (2) Sparks, evidencing a difference of potential of some thousands of volts, produced between the two hands of the same operator. (3) Luminous spiral produced in exhausted glass tube by molecular bombardment from wire spiral wound outside tube. (4) Some effects produced by high frequency discharges passing through semi-conducting substances, and striking liquids.

Sodium potassium high temperature thermometers, and specimens of the alloy, were exhibited by Mr. E. C. C. Baly and Mr. J. C. Chorley. These thermometers are filled with an alloy of sodium and potassium which is liquid at ordinary temperatures. Their range is from 0° to 620°C. (1,150°F.); the softening point of the glass, a specially hard kind, being about 650°C. The separate specimens of the alloy are exhibited to show its purity and its very remarkable surface tension.

Mr. Cecil Carus-Wilson exhibited the scotographoscope, for enabling lecturers to demonstrate with chalk in a darkened room. A compartment encloses a lamp so arranged as to cast a pure white light upon the interior surface of the sheet of specially prepared glass, which forms the front of the apparatus. In a darkened room, on removing the sliding screen, an intensely white surface is exposed, upon which chalks of any colour can be used in the ordinary way. Small chalk drawings easily seen at a distance of 100 feet or more, and they may be rapidly deleted by means of a damp sponge. The whole apparatus folds into a small compass for travelling.

Magnetic curve tracers, were exhibited by Prof. Ewing, F.R.S. The magnetic curve tracer exhibits the relation of magnetism to magnetising force in iron. A mirror, which is free to move both vertically and horizontally, receives two component motions: one (horizontal) proportional to the magnetising force H, and the other (vertical) proportional to the magnetisation B. The reflected light traces the characteristic cuve or B and H, exhibiting the influence of magnetic hysteresis. The instrument at work in the recess shows a cyclic process caused by periodic rapid reversals of magnetising force. A more recent form of the magnetic curve tracer is also shown (made by



Messrs. Nalder Brothers) which is arranged for the commercial testing of iron. The metal whose magnetic qualities are to be tested is made up in rods, which are readily inserted and removed. The rods which are shown are built up of narrow strips of sheet iron.

Prof. A. Smithells, B.Sc., exhibited experiments to demonstrate the structure of flames. (1) The separation of a non-luminous coal-gas flame into two combustion cones is effected by sliding a wider tube over the one on which the flame rests. The products of combustion can be aspirated from the intervening space. (2) Using benzene vapour instead of coal-gas, the transition from a simple luminous flame to a non-luminous flame is shown. The two cones of the latter are separated as before, and by a further addition of air the outer cone disappears, the complete combustion occurring in a single cone. (3) By introducing a spray of a solution of a copper salt, it is seen that the coloration of the flame occurs only in the outer cone where copper oxide is formed. (4) The cone flames are also separated by using a single tube. A platinum wire is pushed up axially till it touches the inner cone. On drawing it down, the inner cone is inverted and follows the wire.

Rev. F. J. Smith, M.A., exhibited an inductoscript. The inductoscript figures and pictures are made by placing the object to be reproduced in contact with an ordinary photographic plate, placed upon a conducting sheet of metal. The object and the plate are connected to the terminals of an induction coil or other source of electricity, for a fraction of a second, and then developed in the usual manner. Several of the pictures shown were produced on plates which had been exposed to full daylight. The pictures marked B were produced by the same method on bromide paper. Non-conductors such as wood blocks are coated with a surface of plumbago before being operated on. The best results are obtained by conducting the process in oxygen gas under a pressure of about two atmospheres.

Platinum thermometers and pyrometers, compensated resistance boxes and galvanometers, compensated barometer and air thermometer, exhibited by Mr. H. L. Callendar; a series of sections illustrating the seasonal distribution of temperature in sea-water lochs, exhibited by Dr. Hugh R. Mill; a portable hydrogen oil safety lamp, adapted for illumination and delicate testing in air containing any kind of inflammable gas or vapour, exhibited by Prof. Frank Clowes, D.Sc.; tuning forks worked electrically, a portable photometer, a table polariscope, exhibited by Sir David Salomons; high tension apparatus, exhibited by Sir David Salomons and Mr. L. Pyke; electrical apparatus, exhibited by Major Holden.

The Marine Biological Association exhibited marine invertebrata from the Plymouth area. Selected specimens of crustacea decapoda, and mollusca opisthobranchiata, including many rare species, and illustrating the richness of the Plymouth fauna.

Dr. G. H. Fowler exhibited specimens of oyster shells. The specimens illustrate:—(1) The rate of growth of the oyster. (2) Natural varieties of the shells. (3) Modifications of a variety bred under new conditions.

Prof. Weldon, F.R.S., exhibited diagrams showing the frequency of variations in the size of certain organs of crabs. The diagrams are based on measurements of portions of the carapace and other parts of *Carcinus mænas.* The organ to which each diagram refers is indicated in the central drawing of a crab. Each diagram is based upon measurements of 1,000 individuals, and the size of the organ measured is indicated (as a percentage of the body length) on the base-line of each. The vertical ordinates of the black curve show the number of individuals having the organ measured of the given magnitude, and the red curve is a probability curve.

Spectra of the flame from a Bessemer converter, exhibited by Prof. W. N. Hartley, F.R.S. The photographs comprise the solar spectrum intended for reference, together with spectra of the Bessemer flame taken at consecutive periods of the "blow" as indicated by the time during which the plate was exposed in each case. The flame spectra will be seen to be composed of (1) a continuous spectrum due to carbon monoxide; (2) a band spectrum belonging to metallic manganese; and (3) a line spectrum principally belonging to iron. Lines of potassium, sodium, and manganese are also present. Taken at the Crewe Works of the London and North-Western Railway Company, by permission of Mr. F. W. Webb, January, 1893. Enlarged ten diameters by the Autotype Company.

Prof. J. Norman Lockyer, F.R.S., exhibited the photographic spectra of some of the brighter stars.

Mr. Isaac Roberts, F.R.S., exhibited five original negatives and enlarged photographs of nebulæ and clusters of stars, taken with the 20-inch reflector by the exhibitor.

Some species of butterflies, illustrating protective mimicry were shown by Colonel Swinhoe. Mimetic forms of the nymphalid genus Hypolimnas in India, Malayana and Africa, showing the various phases of development of mimicry in two widespread species of the same genus; also mimetic resemblances to different protected species in the females of *Euripus halitherses*, &c.

The Zoological Society of London exhibited specimens of lepidopterous insects bred in the insect house of the Zoological Society in London. Four cases containing specimens of *imagines* or perfect insects, raised from *chrysalides* or pupæ in the Zoological Society's insect-house in the season of 1892. They belong chiefly to the silk-producing moths of the family Bombycidæ, and to the diurnal lepidoptera or butterflies.

Remains of extinct birds from New Zealand and the Chatham Islands (off the coast of New Zealand), exhibited by Mr. H. O. Forbes. The exhibit consisted of the chief portions of the skeleton of *Aphanapteryx Hawkinsi* (Forbes), a genus of rails known hitherto only from Mauritius, and of *Palæocorax Moriorum* (Forbes), a large raven, a form not otherwise known in the region; portions of the skeleton of a large *Fulica*, and of a species of swan, now extinct, from the Chatham Islands; a part of the skull of a large Auserine bird allied to *Cereopsis*, found associated with moa remains in a bog in New Zealand; the tibia of a new species of *Cnemiornis*, an extinct giant goose

(*C. gracilis*, Forbes), and the limb bones of three species, belonging to a new genus *Palæocasuarius* (Forbes), of the *Dinornithidæ*.

Dr. D. Sharp, F.R.S. exhibited some ants and their sound producing organs. The sound-producing organs of ants consist of very fine parallel lines engraved on a portion of the outer surface of the chitinous skeleton and of a scraper or very fine edge. Great delicacy of movement may be given to the latter instrument by means of a ball-and-socket joint.

Sections showing the microscopic structure of certain fossil cryptogamic plants from the coal-measures, exhibited by Prof. W. C. Williamson, F.R.S., and Dr. D. H. Scott; white corpuscles of the blood and lymph under the microscope, exhibited by Mr. W. B. Hardy and Dr. A. A. Kanthack; maps and photographs illustrating the Sandgate Landslip, exhibited by Mr. W. Topley, F.R.S., and Mr. R. Kerr, F.G.S.

Mr. Edward Matthey F.C.S. exhibited form in which antimony separates from bismuth at a temperature of 350°C. The specimens are those of the film as removed from the surface of the melted antimonial bismuth. They consist of antimony oxide, containing about ten per cent. of bismuth.

Two compact voltaic batteries of zinc and platinum, were shown by Dr. G. Gore, F.R.S.

Major P. A. MacMahon, F.R.S., exhibited peramutational tesselations. A new method of obtaining designs for tesselated pavements, based upon the property possessed by the twenty-four different isosceles right-angled triangles derived by permuting four designs in all possible ways upon the sides.

Mr. E. Wethered exhibited photo-micrographic lantern slides, illustrating the micro-organisms in limestone rocks. The slides especially illustrate the remarkable structure known as *Girvanella*.

Lord Armstrong, C.B., F.R.S., exhibited experiments to show the nature of the electric discharge in air and water. The experiments will all be exhibited in action on the screen of the electric lantern, and will include the transfer of a cotton string from one vessel to another by means of a current of water flowing within another under the influence of electricity. Various dust figures will also be formed and similarly shown, displaying the nature and effects of the electric discharge in air.

Preparations and photographs demonstrating the action of solar and electric light on the spores of bacteria and fungi, exhibited by Prof. H. Marshall Ward, F.R.S.

THE INTERDEPENDENCE OF ABSTRACT SCIENCE AND ENGINEERING.

ON Thursday evening, May 4, the first "James Forrest" Lecture was delivered at the Institution of Civil Engineers, by Dr. William Anderson, F.R.S. The subject was "the interdependence of abstract science and engineering." After briefly explaining the origin of the lecture, Dr. Anderson proceeded:—The theme which has been prescribed is "The Interdependence of Abstract Science and Engineering," and I imagine that the subject has been chosen because of an uneasy feeling, which possesses many thoughtful men, that this country is not keeping pace with its neighbours in engineering progress, and that we shall, in the future, have to pay more attention to abstract science and its application to practice, than we have been, so far, in the habit of doing.

With rare exceptions, in this country, has there been even a slender amount of theoretical knowledge imparted to various grades of employment; it is only during the last few years that Science Colleges and technical education in schools and People's Palaces, are beginning to bring our operatives up to the level of our foreign friends, but, unfortunately, too late to retain that pre-eminence which we at one time could claim, and, I fear, placed too much confidence in; and moreover, a new danger has arisen in the circumstance that popular scientific education has taken a one-sided direction, that of mechanical and technical knowledge alone, so that, though the operative approaches his work with increased intelligence, he remains unfit to reason out the great economic problems on which his own welfare and that of the nation depend.

It is a matter of extreme surprise to me that so little attention is paid to the science of Political Economy, that not only the mass of the people, in whose hands the voting power now lies, but even, in a great measure, the representatives whom they elect, have no systematic training in, and are grossly ignorant of, the principles which lie at the root of national prosperity. The further misfortune follows that politicians of the highest position do not scruple to trade on this ignorance, or pursue a course which, in its consequences, is as bad—being ignorant themselves they strive to lead the ignorant, and set the operative against his employer and against society in general. The cheapness of newspapers, their wide diffusion, and their blind, not to say reckless advocacy of popular fallacies acting on the ignorance, prejudices, and discomfort, if not suffering, of the operative classes, are giving enormous power to trade organisations, whose avowed object it is to improve the earnings and social standing of the operative at the expense of, or at any rate without regard to, the interests of every other class in the community, and this is to be accomplished not by encouraging education, not by advocating thrift and temperance, not by urging the workman to improve his mechanical dexterity, the thoroughnesss of his work and the amount which he produces, but by holding out visions of shortened hours of labour, by compelling a minimum of pay which will enable him to live in comfort, of systematically restricting the amount of work done by each individual, even in the shortened day, all under the fatal illusion that by such means a greater number of men will find more remunerative employment.

The employer is usually credited, by the trade leaders, with accumulating wealth without effort, risk, or anxiety, by the slavish labour of his operatives, while the proofs to the contrary, so easily to be obtained in the slender dividends declared by most industrial enterprises, and in the records of the Bankruptcy Courts, are steadily kept out of view.

There would be no fault to find with the new class of professional agitators, who live by the discontent which they foment, were they, and the Unions which they manipulate, to contribute in the smallest degree to the obtaining of that work and of those orders, in the execution of which the wage-earning portion of the community have their being. This, the most difficult part of every commercial enterprise, is left to the much-abused capitalist, so that the absurd and impossible system is fast asserting itself, that professional skill, mercantile ability, and capital, shall obtain the work, and run all the risk of design, execution, and financial security; but that work shall be carried out according to rules which self-constituted and perfectly irresponsible bodies choose to impose. The smallest acquaintance with the principles of political economy would demonstrate that such methods must end in ruin, that they are utterly incompatible with our policy of Free Trade—a system which is perfectly reasonable and proper if thoroughly carried out, and which certainly never contemplated the protection of one particular class, and that, not by edict of the State, but at the bidding of self-constituted tribunals whose claims amount to this:—that there shall be free trade in all products which the operatives require to buy, but the strictest protection as to all that they have to sell, namely their labour, and whose ultimate methods are violence, and the coercion of all who differ from views which many intelligent but timid workmen know to be at variance with the true interests of their class.

Under all this lies the socialistic idea of equality in the condition of every member of the community, an idea which political economy demonstrates to be utterly Utopian and impossible. Since the creation of mankind the differences in social position and in material comfort which follow naturally from the endless variations of mental and bodily powers in men, have existed, and, in spite of many abortive attempts, more or less violent, to establish equality, will exist for ever; for it seems to me that the doctrine of Carnot with respect to heat-engines applies by analogy to the question of national prosperity. To obtain mechanical power from a source of heat there must be a fall of temperature, and the greater that fall is the more efficient will the engine be—a dead level of temperature simply means extinction of energy and of life. To ensure active trade and prosperous manufactures there must be a fall of money or of its equivalent from the wealthy to the comparatively poor, the one class is absolutely essential to the other; the prosperity of the community is bound up in the existence of these differences, and a dead level of wealth would be a dead level of poverty, which would end, as a state of uniform temperature must end, in absolute stagnation and death.

However much we may regret the inequality which exists in the distribution of wealth and comfort, it is just as much a law of nature as the unequal distribution of warmth, of sunshine, or of rain, and seems to me to follow naturally and inevitably from the endless variations in the physical, moral, and mental powers of human beings, and therefore to be as unalterable at the bidding of man as these attributes are. It only remains for us to recognise the fact, to make the best of it, and to avoid the gross wickedness of attempting to delude the poorer and more ignorant members of the community by incessant representations that it is the greed and selfishness of the wealthy which keep them low.

If the so-called "working man" be the embodiment of all that is needed for the industrial prosperity of a country, and if the possession of capital and the far wider consequence, the existence of credit, be a crime, why does he not arise in his strength and exhibit the faculties of combination which are so well illustrated in the trades unions, and establish engineering works and manufactories, or undertake engineering enterprises from which he will be able himself to reap the golden harvest which the capitalist and the shareholder are supposed to gather, and who thereby excite his envy and arouse his hatred.

In deference, I presume, to the immense numerical importance of the operative classes, politicians are vieing with each other in supporting the impossible claims put forth—claims which, if conceded, will only precipitate the ruin of the class they profess to benefit, and which already is the form of what may be termed benevolent legislation in favour of the operative, is heaping up elements of cost which our productive energy is unable to bear. The absurd cry that manual labour is the sole source of wealth has been well combated by that acute reasoner, Mr. Macfarlane Gray, who, in a recent discussion on the labour question, happily compared the body politic to a tree. The popular belief is that plants are nourished through their roots, which for that reason are believed to be the all-important parts, while the leaves are mere ornaments, enjoying the upper air and sunshine and profiting by the work done underground. But a juster knowledge, one of the fruits of abstract investigation, tells us that the roots are mainly useful in holding the tree erect, and have comparatively little to do with providing the materials for building up its structure. It is the leaves which form the great laboratory in which the main components of the plant are extracted from the region where superficial observers would least expect to find them—namely, from the atmosphere. He compares the roots to the operatives' part of the community; the trunk and leaves to the monetary, the scientific and the commercial part which drew from far and wide that which is necessary to keep the growth advancing and maintain it in health. The roots may just as well claim to be the sole sources of life in the tree as the operatives may claim to be the only producers of wealth, and conversely the leaves could, with as much reason, consider themselves as the only essential portion of the plant as the merchant or the capitalist claim to be independent of the operatives. Each grade in the body politic is essential to the other; it is an axiom that there can be no degrees of comparison between essential parts; and those who, from ignorance or from interested motives, persistently preach the doctrine of the superior importance of the "masses" over the "classes" are inflicting a deep injury on the prosperity of the country, and especially on those whom they so grossly flatter.

Nothing, save bitter experience, will alter the course of events. It seems to be the fate of peoples to attack social problems from the wrong end, to solve them by the painful and dilatory process of trial and error, rather than by means of investigation based on first principles. And this method is commonly applied to engineering problems also. Random trials, as a rule, are the methods by which great results have been achieved, while the application of the scientific principles involved have been left to other heads long after the results sought have been attained at much needless cost, and by much unnecessary expenditure of labour and of time.

It is not often that a genius of the order of James Watt rises in the mechanical world. Up to his time the "fire-engine," as it was most properly called, was being slowly developed without any exact knowledge of the properties of the agent by means of which the heat generated by the combustion of fuel was converted into work, and this in spite of the circumstance that such a master mind as that of Smeaton had been directed to perfecting the new method of utilising the potential energy of fuel, and of applying it to engines of large power, and on an extensive industrial scale.

The lucky chance which presented itself of having to put in order a working model of a Newcomen engine illustrates in an interesting manner how, in pursuance of his business, he quickly executed the necessary repairs and alterations, and afterwards, at greater leisure, attacked the problem which the failure of the model presented, from the theoretical side, but soon found that the then state of knowledge did not afford the means of explaining the failure, and compelled him to set about the determination of such elementary data as the specific volume of steam, the latent heat of evaporation, and the law of tension of steam under varying temperatures. In the astonishingly short period of two years, and with the rudest and cheapest apparatus, he had furnished himself with the abstract knowledge required for explaining in a definite manner the action of the steam engine, and he had no difficulty, as soon as his theoretical ground was sure, in determining what mechanical arrangements were necessary to realise the conditions imposed by science. From investigations apparently of an abstract or non-practical character, sprung at once the separate condenser, the closed cylinder and the equilibrium working of a single-acting engine, the steam jacket, the air-pump, the theory of expansive working, the function of the momentum of the moving parts, and the exact calculations based on first principles by means of which the proportions of engines could be fixed, and the quantities of steam, water, and of fuel calculated. Watt, of course, was a born mechanic, as well as a seeker after physical knowledge. The workshop in his house near Birmingham, happily preserved to this day as he left it, shows that his mind was ever bent on mechanical contrivances which his own hands were skilful enough to carry out; his valve-gear, the stuffing box, the parallel motion, the governor, are all instances of that happy blending of mechanical skill and of scientific research which must ever mark the qualifications of a great mechanical engineer.

A contrast to Watt's achievements is the singular history of the development of iron and steel bridge building, which necessarily followed the introduction of railways. Watt felt the want of first principles by which to shape his actions, and set about discovering them; but the principles which underlie the determination of stresses in braced structures, such as roofs and frameworks of various kinds, as well as those in solid bars subjected to the action of transverse forces, have long been known; and early in this century Navier made them the subjects of lectures at the École des Ponts et Chaussées, yet engineers in this country seem to have been but dimly aware of them, or, at any rate, to have made little use of the knowledge which was at their disposal. It is difficult, from the published histories of such enterprises as the Conway and Britannia bridges, to arrive at any conclusion as to the extent of knowledge, or rather ignorance, which existed among engineers before these works were commenced. It is sufficiently evident, however, from the long series of purely tentative experiments by which the proportions of the Conway and Britannia bridges were determined, as well as from the singular vagaries to be noticed in the smaller bridges of that day, that only the haziest ideas of the disposition of stresses, and of the functions of the component members of girders existed.

In the experimental investigations of the time, the function of the web or vertical member of a girder was completely ignored, for it was looked upon merely as the means of keeping the top and bottom flanges in their relative positions, while the essential difference in effect of a uniformly distributed load, or of a rolling load, as compared with a load concentrated at the centre, on the vertical member of a girder, and even on the flanges, appears to have been overlooked till made evident by the results of experiment. Yet the principle that a force cannot change its direction unless combined with another force acting in a direction inclined to it, was perfectly well known, and should have led to the discovery that it is only by diagonal stresses in the vertical members that the load resting on a beam can be transmitted to the abutments; that the stresses due to loads concentrated at the centre were very different to those arising, both in the vertical web and in the flanges, from the action due to a load distributed in a given manner along the top or the bottom flanges, and that a rolling load would produce effects peculiar to itself.

The girder with diagonally braced webs, or the lattice girder, as it is commonly called, appears to have had its origin in Ireland; at any rate it was in that country that it received its earliest and chief development; and in the hands of Wild, Barton, Bow, and Stoney, the true principles began to assert themselves, and Mr. Barton's Cusher River bridge, of 70 feet span, on the Great Northern of Ireland Railway, was probably the first example of a lattice girder in which the cross-sections of the members of the webs as well as those of the flanges were correctly proportioned to the stresses imposed by a rolling load. This comparatively small bridge was followed by the Boyne viaduct at Drogheda, which must ever rank as a signal illustration of the successful application of abstract principles to a great work by men who were capable, not only of appreciating them, but of following their guidance in a practical manner.

The wrought-iron portion of the viaduct consists of three spans, the main girders of which are continuous; and the points of contrary flexure in the middle, and larger span, were determined by direct calculation, the correctness of which was demonstrated in the actual structure by setting free the plates of the flanges at the points indicated, and by observing the opening and closing of the plates so disunited when the land ends of the girders formimg the side spans were raised or lowered.

Mr. Wild appears to have been the first to demonstrate correctly the distribution of stresses under any disposition of load in the Warren girder, a form of beam in which the web is composed of a single system of diagonal bracing inclined at an angle of about 60°. In the museum of Trinity College, Dublin, there has existed since, I believe 1854, a model of a Warren girder, 12 feet 6 inches long and 12 inches deep, in which the tension members both of the flanges and diagonal bracing are so arranged and articulated that any one section can be taken out and a spring balance inserted, by means of which it can be demonstrated that the stresses calculated for any disposition of load do actually arise.

The history of scientific research teems with instances of discoveries which at first seem to have had no practical value, but which nevertheless have ultimately proved to be of the utmost importance to the engineer. For example, the changes of temperature which occur in many chemical reactions were merely noted at first as interesting accompaniments to such reactions; but, by degrees, it was perceived that the amount of heat evolved or absorbed in each change was a constant and definite quantity, capable of exact measurement, and in process of time the thermal values which characterised a vast number of chemical changes were determined, and are now considered of cardinal importance in many industrial operations, and constitute the science of thermo-chemistry, and render it possible to judge of the efficiency of a boiler, for instance, when the rate of fuel combustion and that at which the water was heated or evaporated were known, by calculating the proportion which the heat imparted to the water bore to that produced by the combustion of any fuel of which the chemical composition had been ascertained, and from which the heat capable of being developed could be calculated by general rules.

One practical effect of the exact knowledge which every competent engineer now possesses on this subject, or can easily obtain, is that inventors have ceased to squander their time and their means in seeking for impossible high boiler duty, and the public is no more entreated to try contrivances which are to save at least 50 per cent. of the fuel they use, because inventors know that the testing of boilers is now usually carried out by experienced and educated men, who, by very simple and inexpensive trials, obtain the data by means of which they can calculate with certainty how much scope for improvement actually exists.

Still more remarkable perhaps is the application of thermochemistry to the complicated reactions in the blast and regenerative furnace, and the valuable conclusions arrived at in consequence by such thorough and patient investigators as Sir Isaac Lowthian Bell, Sir William Siemens, Charles Cochrane, and others who have succeeded in equating the heat-units resulting from the oxidation of fuel to the ultimate thermal results of the decomposition of the ore and fluxes, showing thereby the limits of economy which the ironmaster may hope to reach, and the proportions of the furnaces in which his expectations may be realised.

No less valuable have been the fruits yielded by the discovery of the great law of the Conservation of Energy, and by the recognition of the fact that, though energy cannot be destroyed, it may be made to assume various forms, and may be rendered either dormant or active. The sun's rays, aeons of ages ago, during the dense vegetation which characterised the period of the coal measures, expended their energy in tearing asunder the carbon and oxygen of the carbonic acid distributed through the atmosphere, and in storing the carbon, thus endowed with potential energy, in the deposits whence we now derive our coal supplies. By suitable arrangements this dormant energy is quickened into that quality of motion which we recognise as heat, and which, setting into sympathetic vibrations the material of the furnace-plates and smoke-flues of boilers, operates on the surrounding water, the molecules of which, under this influence, assume the more extended movements of the highly elastic substance which we know as steam. The products of combustion, on the one hand, are restored to the atmosphere, their remaining store of heat is slowly dissipated, while the carbonic acid gas produced in combustion is again ready to present itself, in the green leaves of plants, to the decomposing action of the sun, and by that means the carbon and the oxygen become once more sources of heat. The steam produced, on the other hand, communicates its molecular motion to external bodies in various heating operations, in the visible motion and force of the steam-engine or into the slower dissipation through space or over the earth, whereby it is again condensed to water and returned to its normal condition, while the energy, for the exhibition of which, Carnot has taught us, steam was the mere agent, becomes transformed into masses of water lifted, into air compressed, into electrical currents generated, into mechanical work done, or into the heat developed by friction; but the general tendency is towards dissipation under the form of heat into space, the waste being made good by the stores of heat poured on to our planetary system by the huge and mysterious body which is its centre.

But modern investigators, and, most of all, engineers, are not content with vague statements such as I have just made; they hold with the motto of the ancient Society of Civil Engineers, "Omnia in numero pondere et mensura," and they are therefore greatly indebted to Rumford, Carnot, Davy, Mayer, and Joule, who not only showed that heat was a "mode of motion," but determined by tedious and delicate experiments its mechanical equivalent.

And what is now the result?

When examining heat-engines or other applications of heat in the arts, the engineer collects the apparently aimless work of half a century, and of many minds, and finds himself able to construct a balance sheet by which he can show on the Dr. side, to a fraction, the quantity of heat he has received, and on the Cr. page, with astonishing precision, the manner in which that heat has been expended. This method of treatment is not only lucid, but it is self-checking, and it points out exactly how much heat has been uselessly dissipated, and consequently in what direction improvements may be made, and it indicated further, the limits within which it is alone possible to make advances in economy.

These general principles apply even to the conversion of heat into the work done in the bore of a gun. The enormous pressures which require to be developed in order to impress high velocity on the projectile in the necessarily limited length of the barrel, the shortness of the time of action, and its violence, render it extremely difficult to obtain accurate and trustworthy records of pressures along the chase of a gun by direct methods; but by invoking the aid of the chemist and of the physicist in first ascertaining the properties of the explosive, that is to say, the specific volume of the gases, the quantity of heat evolved during combustion, and the specific heat of its products at high temperatures, it becomes possible to calculate curves of mean pressure which will account for the energy imparted to the projectile and to the expelled gases, although the question of abnormal local pressures, due apparently to the mode of ignition of the charge and the rate at which explosion is propagated through it, will not be revealed. This process is made the easier, in the case of smokeless explosives, because the products of combustion are wholly gaseous and retain that condition till expelled from the bore.

One of the loftiest of abstract conceptions relating to the structure of the universe, the product of many acute minds of this century, is the imagining of a substance of infinite tenuity but of immense elasticity, which permeates all space and every substance. It cannot be seen, or felt, or weighed, its composition is unknown, it cannot be pumped out of a closed vessel, it does not appear to offer any resistance to the motion of planetary bodies, and its existence is only made manifest by its property of transmitting chemical rays, light, radiant heat, electricity, and probably some more recondite forms of energy, at enormous velocity from the remotest regions of the universe and by means of vibrations the nature of which, the astounding frequency and minute pitch, have been determined by mathematicians. It is pardonable in human beings to disbelieve in the existence of the luminiferous ether, even though the profoundest thinkers and most successful workers of the present day may have all the conviction of Lord Kelvin, who has declared that "it is the only substance that we are confident of in dynamics, the one thing we are sure of is the reality and substantiality of the luminiferous ether!"

But what has the Engineer to do with such speculations, and what does it matter to him how light and heat are transmitted from the sun or from the stars, or by what mechanism heat, magnetism, and electricity are diffused over the earth? This question is being answered already in our daily practice, and is destined, no doubt, to receive fuller and more convincing response as time rolls on. I will give one or two instances. The study of the spectrum produced by the passage of light through triangular prisms has revealed the fact that the ordinary rays of white light are of a complex nature, that only a portion of them are discernible directly by the sense of sight or by that of feeling, while the ultra-violet rays can only be seen in their action on Uranium glass, or in the chemical decomposition they produce in certain substances. But, further, the spectrum viewed by modern instruments is found not to be continuous; it is crossed by dark, by light, and by coloured bands, which the patient researches of Fraunhofer, Kirchhoff, Huggins, Norman Lockyer, and others, have shown by their position, thickness, or colour to characterise certain glowing substances, and by comparison with the spectra produced by heated terrestrial solids and gases, it has been proved that many of the elements in the sun and in the stars are identical with those with which we are familiar on this earth, and this knowledge has served in a striking manner to confirm the correctness of the nebular theory as to the origin of our planetary system.

Not only have a large number of terrestrial elements been discovered in the sun, but the spectroscope has revealed, to a large extent, the order in which they are arranged on the sun's surface, and this leads to the conclusion that at one time a similar order prevailed on the earth, and therefore throws some light on the deep geology of our planet.

One of the practical outcomes of these discoveries has been the theory of Mendeleeff on the origin of petroleum, a theory of the utmost importance to the human race, and to our country in particular, in view of the inevitable exhaustion of our coal supplies, for it asserts that petroleum is the product of the action of water on the carbides of metals at high temperatures at no very great relative depths in the crust of the earth, that this production is continually in progress, and that deposits thus actually forming may be reached in many places by sufficiently deep borings; and in view of recent progress in mechanical skill, it certainly would be rash to say that borings of immensely greater depth than any that we are as yet acquainted with will never be made, for if accumulated evidence as to the correctness of Mendeleeff's views together with the ever-increasing cost of fuel, shall hold out hopes of success, enterprising men will be found ready to embark their means in undertakings, the risks of which would not seem to be more formidable than those which surrounded the laying of the first Atlantic telegraph cable, and the rewards of success in which would be incomparably greater.

The researches of Roberts-Austen, of Osmond, Le Chatelier, and others, are slowly, but it is hoped surely, establishing laws by which the relative atomic volumes of ingredients will become a guide to the nature of their mutual interaction, and it seems probable that spectrum observations which are of such value in gauging the purity of the materials dealt with, will come in aid and in support of the indications given by automatically traced curves of rates of cooling, which have given such a deep meaning to the phenomenon of recalescence, a property of iron and steel which for many years remained a mere laboratory curiosity.

Many bodies, including metals and their alloys, may exist in more than one form; sulphur, for example, assumes two allotropic states, but at ordinary temperatures and in a comparatively short time the one condition passes into the other Mr. Addenbrook has recently prepared an alloy of aluminium, and nickel, which when freshly made possesses considerable tenacity, but which, after a few hours, crumbles into powder. The researches of Osmond seem to show that pure iron also can exist in two states—one very hard, the other soft, and it is more than probable that these states merge into each other under certain conditions of heating or cooling, or under the influence of foreign substances. There can be no doubt that steel also, in course of time, undergoes molecular change at ordinary temperatures, and possibly under the influence of strains produced by internal stresses due to unequal rates of cooling. It is a common opinion, based on experience, that tool steel should not be used as freshly made, but should be kept some months, and the same precaution applies to dies used in coining and similar operations, and to armour-piercing shot, both of which, having been hardened by necessarily unequal and rapid cooling, either accommodate themselves to the stresses engendered by slow changes in the motion of the molecules, or fail spontaneously even after months of repose. Glass undergoes similar changes, and generally materials which have been severely strained either by the external application of force, or by heating, will only gradually recover their normal condition. This has been beautifully demonstrated by Prof. Hughes, with the aid of his induction balance, on specimens of the narrow steel ribbon used in the manufacture of Longridge wire guns. A number of specimens recently submitted to him showed a remarkable uniformity of structure, but when heated to only 100° and examined immediately on cooling to the normal temperature, a distinct change was observable, yet after a few hours' rest the material returned to its normal state. If such changes are measurable in ribbon $\frac{1}{4}$ in. × $\frac{1}{16}$ in. in cross section, what may not be the molecular conflict in large masses? These may be produced by alternations of stresses as well as by changes of temperature, and point to the necessity of assisting the molecules and atoms to adjust themselves, or to return to a normal condition by raising the temperature of the substance to about the point indicated by *b* on Chernoff's scale, below which no change in the nature of crystallisation takes place, no matter how slowly the mass is allowed to cool. This principle is recognised in many ways in the arts. In drawing wire or in solid drawn metal-work, such as tubes and cartridge-cases periodical annealing must be resorted to; moreover, experience has shown that crane-chains, for example, should be annealed from time to time if they are to be used with safety; and Mr. Webb has adopted, with the best results, the plan of treating in a similar manner the moving parts of his locomotives after they have run a certain number of miles.

I feel convinced that the frequent disasters with screw propeller shafts, especially after they have been some time in use, arise from the failure to recognise the practical bearing of the tendency to molecular change under the influence of strain and temperature. A propeller shaft is subject to constant variations of stress due to the action of the cranks of the engine, to similar variations caused by the inertia of the screw, and again to a totally different set of stresses which may often be alternately tensile and compressive, due to the wear of the journals and to the working of the hull. The remedy, I feel convinced, lies in the periodical annealing of the material which must of necessity be so hardly used.

I think that it is now generally acknowledged that the luminiferous ether is also the medium by which electrical energy is transmitted by some kind of vibratory motion; hence the ease with which heat or mechanical work is transformed directly into electric currents in the thermopile, or in the frictional electrical machine, and the reasonableness of the great generalisation that we are living on a huge magnet—the poles of which are not far from coinciding with the poles of the earth.

Any one who doubts the value of abstract science should study the construction of the mariners' compass, and especially in the improved form introduced by Lord Kelvin; let him compare the blind groping after correction for the local attraction of the ship with the beautiful and simple theory which has rendered that correction not only easy but readily adapted to changes in the ship's position in the world; he will find that there is not a more striking instance of the profoundest abstract knowledge blended with the power to turn it to practical use, than in this and in so many other labours of the distinguished man whom I have named more than once, and whom this institution is proud to number among its honorary members.

I would now draw your attention to a startling consequence of the undulatory theory in the power which exists of exercising influence, by what is termed induction, at great distances. Animated by the conviction that electric energy was transmitted in the same manner and by means of the same all-pervading medium as radiant energy, and that the distance to which its effects would reach should be unlimited, though the appreciation might be a question of the delicacy of instruments, Mr. Preece has succeeded in sending messages by Morse signals across the Bristol Channel between Lavernock and Flatholme, a distance of over three miles. The electro-magnetic disturbances were excited by primary alternating currents, having a frequency sufficient to generate a low musical note in a telephone, in a copper-wire 1237 yards long, erected on poles along the top of the cliff on the mainland. The radiant electro-magnetic energy was transformed into currrents again in a secondary circuit of 610 yards long, laid along the island parallel to the first and at a distance of 3·1 miles; the messages were read off on the island through the instrumentality of the induced currents.

Any one who has meditated deeply on the nature of the luminiferous ether and on its universal presence has probably felt that it must also be concerned in the action of the human brain. The mechanisms of the "five gateways of sense" have been worked out by anatomists and physicists, but their researches are incompetent to declare how the impressions sent along the nerves at last reveal themselves as images or perceptions in the mind. Lord Kelvin has discoursed on this matter; he has suggested the existence of a magnetic sense, and has shown that the mind may be influenced independently of the recognised organs of perception. There are undoubtedly occult phenomena which can only be accounted for by the supposition that one mind can interact upon another, even as Mr. Preece's parallel wires acted on each other.

Setting aside the immense amount of calculated delusion and imperfect observations which has characterised animal magnetism, clairvoyance, &c., though probably not more than astrology, necromancy, transmutation of metals, and other delusions, hampered the early advance of physical and chemical science, there still remains a substantial amount of authentic fact on which argument may be founded. Prof. Oliver Lodge drew attention to the matter in his Presidential Address to section A at the meeting of the British Association in Cardiff in 1891, and in the opinion of that acute investigator the subject seems to deserve the attention of scientific societies.

It is less than fifty years since the nature of epidemics and the mode of their propagation seemed to be beyond the reach of human comprehension, and when Pasteur commenced his classic investigations into the causes of fermentation and of contagious disease, no one, I presume, thought that such an abstruse study as bacteriology could ever be of the least interest to engineers, nor would they have thought that the controversy relating to spontaneous generation, which raged so fiercely only a few years ago, could have influenced the science to which they were devoted.

But the triumphant demonstrations of Pasteur, of Lister, of Burdon Saunderson, of Tyndall, and of many other workers at home and abroad have shown that there is no such thing as spontaneous generation; that zymotic diseases, those scourges of animal and vegetable life, are caused by living organisms whose modes of propagation and of travel are being eagerly studied, and are day by day being better understood; they have shown that we are no longer fighting at random against an unknown and covert enemy, but are face to face with a subtle foe, whose tactics we are rapidly learning to understand. We have discovered that his best allies are to be found in the carelessness of his victims as to cleanliness, to drainage, and water supply, and that his most formidable enemy is the engineer, who, being guided by the abstract investigations of the biologist and the chemist, can select with certainty the most fitting source of potable water, and can get rid of the sewage of centres of population, not only without inflicting injury on the surrounding community, but very often actually benefiting them by removing existing sources of pollution and by increasing the productiveness of the soil.

But not alone in sanitary matters has bacteriology produced profitable results; it may truly be said that the great industries of brewing, of wine and vinegar-making, and many other manufactures, have been placed on a sound footing by the knowledge we now possess of the occult action of ferments and of bacteria; and even in agriculture the true nature of the operations which take place in soil, by which the nitrogenous food of plants is rendered capable of assimilation, is one of the triumphs of the research of these our days. Schloesing, Müntz, Pasteur, Munro, Percy Frankland, and others, have shown that one of the most important of plant-foods in the soil is nitric acid, and that this substance is elaborated from ammonia by the action of minute living organisms. The singular fact has been demonstrated that the work is performed by a system of division of labour, one kind of bacterium converting the ammonia into nitrous acid and declining to do any more, when another species takes up the work and produces nitric acid, which presents the nitrogen in a form which can be assimilated by the plant. "Not only," to use the words of Dr. P. Frankland, "is this process of nitrification going on in the fertile soils, but enormous accumulations of the products of the activity of these minute organisms in the shape of nitrate of soda are found in the rainless districts of Chili and Perú, from whence the Chili saltpetre, as it is called, is exported in vast quantities, more especially to fertilise the overtaxed soils of Europe!" But more than that, long and patient research has established the fact that, in certain of the legumenous plants, the same microscopic agency acting in the roots endows them with the power of assimilating the nitrogen of the atmosphere, and by that means makes them the instruments for actually enriching the soil instead of exhausting it.

I have already alluded to the circumstance that the engineer cannot be satisfied with vague statements or with mere abstract opinions. The very nature of his calling implies action; he has to construct, his works must be stable, his machinery must act, his estimates of cost and of the consequences of his operations must come true, and hence he has to make a close alliance with that most fascinating and fruitful of the sciences—mathematics. It is not given to many to possess the peculiar aptitude which leads up to the highest investigation, but neither has the engineer often need of anything deeper than almost elementary knowledge, especially if he gets into the habit of working out the problems that come before him by the graphic methods which are now so assiduously cultivated, and if he will realise that slovenliness in the matter of calculations commonly leads to disastrous results. Though his attainments may not be high, and though disuse may have made it difficult to wield the power which knowledge, early acquired, once gave him, yet he can always appreciate and put his faith in the great minds which delight in subjecting the theories of physicists to the rigid test of mathematical analysis, and thereby stamping them with the seal of irrefragable fact.

One great quality he must possess, especially in these days when numerous science colleges have rendered high mathematical training of easy access—and that is common sense. There is a tendency among the young and inexperienced to put blind faith in formulæ, forgetting that most of them are based upon premises which are not accurately reproduced in practice, and which, in any case, are frequently unable to take into account collateral disturbances, which only observation and experience can foresee, and common sense provide against.

I have endeavoured to show how the history of abstract science, by which I intend to designate the history of researches entered into for the sole purpose of acquiring knowledge of the operations of Nature and of her laws, without any thought of reward, or expectation of pecuniary advantage, has had its reflex in the records of the engineering profession, and how the most recondite investigations, apparently unlikely to have any direct influence on our practice, have, in course of time, become of cardinal importance. I have also ventured to point out how, in these days, the engineer must banish from his mind the idea that anything can be too small or too trifling to deserve his attention. "Nothing is too small for the great man," is, I am told, written over the cottage once occupied by Peter the Great at Saardam. The truth embodied in that legend should ever dwell in our minds; for success, I am persuaded, lies largely in close attention to details.

The discourse concluded by a warm tribute to the merits of the old servant of the Institute who had established the lectureship.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—It is proposed to appoint a Syndicate for the purpose of considering the desirability of establishing an examination in agricultural science, open to all trained students, whether members of the University or not. The successful candidates in such an examination would receive a University diploma similar to the existing diploma in Public Health. It is understood that this plan has received the approval of the Royal Agricultural Society and the Board of Agriculture. These bodies, and certain of the County Councils, have further agreed to subsidise a scheme for the regular instruction within the University of candidates for the examination if it be established.

SCIENTIFIC SERIALS.

American Journal of Science, May.—Deportment of charcoal with the halogens, nitrogen, sulphur, and oxygen, by W. G. Mixter. The tenacity with which charcoal retains hydrogen even after ignition in chlorine makes it difficult to decide whether certain gases absorbed by charcoal are occluded or chemically combined with it. Experiments performed on sugar-charcoal, gas carbon, and "Diamond Black," a variety of lampblack derived from natural gas, indicate that chlorine does combine with charcoal, but that the combination is brought about by a replacement of the hydrogen. Pure native diamond and graphite do not take up chlorine, while iodine and bromine are not absorbed even by impure charcoal. Nearly pure amorphous carbon takes up but little sulphur, while a soft charcoal containing much hydrogen and oxygen combines with a considerable amount, taking it up even from carbon bisulphide.—Note on some volcanic rocks from Gough's Island, South Atlantic, by L. V. Pirsson. An examination of beach pebbles from the shores of this craggy island, 240 miles S.E. of Tristan da Cunha, establishes its recent volcanic nature, and thus adds one more to the line of mid-Atlantic volcanoes which, sweeping southward through the Azores, Cape Verde Islands, Ascension, St. Helena, and Gough's Island, terminates on Bouvet Island on the confines of the Antarctic Ocean.—The influence of free nitric acid and aqua regia on the precipitation of barium as sulphate, by Philipp E. Browning. In the presence of nitric acid to the extent of 5 per cent. very little solvent action is shown, and the sulphate may be safely filtered after an hour's time. Even with 20 to 25 per cent. the solubility does not exceed 0·001 grm. on the average. Aqua regia has even less solvent effect, and the presence of ten per cent. of either is a positive advantage since it gives the precipitated sulphate a coarsely crystalline form.—On a rose-coloured lime-and-alumina bearing variety of talc, by Wm. H. Hobbs. A talcose mineral was found developed in some specimens of white crystalline dolomite from Canaan, Conn., on lines evidently corresponding to fracture planes in the rock. One of the specimens had a deep rose colour, the other was nearly white, having lost its colour by exposure to light. The mineral was shown to belong to the talc family by its chemical composition and its physical properties, but it differed from known varieties by its colour, its high percentages of lime and alumina, its low fusibility, and by its being easily decomposed by acids.—Also papers by Messrs. A. M. Edwards, A. W. Whitney, S. T. Moreland, S. L. Penfield, N. H. Darton, and M. I. Pupin.

Bulletin of the New York Mathematical Society, vol. ii. No. 7 (New York, April 1893).—The contents are a review, by J. Harkness, of Prof. Greenhill's "The Applications of Elliptic Functions" (pp. 151–57), in which, though there is much appreciative commendation, there is also the *amari aliquid* to add pungency to the criticism.—Next comes a further contribution, the third, on the non-Euclidian Geometry (pp. 158–61), this time by Prof. W. Woolsey Johnson.—The remaining articles are a notice of the Lehrbuch der Ausgleichsrechnung nach der Methode der Kleinsten Quadrate of Dr. Bobek, and the theory of errors and method of least squares of W. Woolsey Johnson, by Mansfield Merriman (pp. 162–63); and two notes (1) on the definition of logarithms (*i.e.* the definition given by Prof. Stringham in the *Amer. Journ. of Math.*, vol. xiv.), by Prof. Haskell; (2) a note on the preceding note, by Prof. Stringham (pp. 164–70).—The number closes with general notes and list of new publications.

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 9.—"The Electrolysis of Steam." By J. J. Thomson, M.A., F.R.S., Cavendish Professor of Experimental Physics in the University of Cambridge.

The following explanation of the results of the experiments seems to the author to be that which agrees best with preceding investigations.

When an electric discharge passes through a gas the properties of the gas in the neighbourhood of the line of discharge are modified. Thus, as Hittorf and Schuster have shown, the gas in the neighbourhood of the discharge is no longer an insulator, but can transmit a current under a very small potential difference. Faraday's remark, that when once a spark has passed through a gas the passage of another following it immediately afterwards is very much facilitated, is another example of the same thing. We have thus good reasons for believing that when a spark passes through a gas it produces a supply of a modification of the gas, whose conductivity is enormously greater than that of the original gas. I have shown ('Phil. Mag.,' November 1891) that the conductivity of this modified gas is comparable with that of strong solutions of electrolytes. When the discharge stops, this modified gas goes back to its original condition. If now the discharges through the gas follow each other so rapidly that the modified gas produced by one discharge has not time to turn to its original condition before the next discharge passes, the successive discharges will pass through this modified gas. If, on the other hand, the gas has time to revert to its original condition before the next discharge passes, then the discharges pass through the unmodified gas; we regard this as being accomplished by means of successive decompositions and recombinations of its molecules, analogous to those which, on Grotthus' theory of electrolysis, occur when a current passes through an electrolyte.

We regard the arc discharge as corresponding to the first of the preceding cases where the discharge passes through the modified gas, the spark discharge corresponding to the second when the discharge goes through the gas in its unmodified condition.

From this point of view, the explanation of the results of the experiments on the electrolysis of steam are very simple. The modified gas produced by the passage of the discharge through the steam consists of a mixture of hydrogen and oxygen, these gases being in the same condition as when the arc discharge passes through hydrogen and oxygen respectively, when, as we have seen, the hydrogen behaves as if it had a negative charge, the ovygen as if it had a positive one. Thus, in the case of the arc in steam, the oxygen, since it behaves as if it had a positive charge, will go to the negative, while the hydrogen, behaving as if it had a negative charge, will go to the positive electrode. We saw that this separation of the hydrogen and oxygen took place.

The correspondence between the quantities of hydrogen and oxygen from the electrolysis of the steam and those liberated by the electrolysis of water shows that the charges on the atoms of the modified oxygen and hydrogen are the same in amount, but the opposite in sign to those we ascribe to them in ordinary electrolytes.

In the case of the long sparks where the discharge goes through the steam, since the molecule of steam consists of two positively charged hydrogen atoms and one negatively charged oxygen one, when the molecule splits up in the electric field the hydrogen will go towards the negative, the oxygen towards the positive, electrode, as in ordinary electrolysis.

April 27.—"On the Coloration of the Skins of Fishes, especially of Pleuronectidæ." By J. T. Cunningham, M.A. Oxon., Naturalist on the Staff of the Marine Biological Association, and Charles A. MacMunn, M.A., M.D. Communicated by Prof. E. Ray Lankester, F.R.S.

The anatomical analysis of the structural coloration elements having not previously been adequately carried out, we have described these elements as they are found in the Pleuronectidæ and various other fishes. In the former family there are two kinds of chromatophores, the black and the coloured, the latter usually of some shade of yellow or orange. The coloured elements in the skin on the upper side are chiefly developed in the more superficial layer immediately beneath the epidermis and for the most part outside the scales, and on the inner side of the skin in the subcutaneous tissue, the rest of the skin being almost destitute of these elements. In the superficial layer the iridocytes are somewhat polygonal plates of irregular shape, distributed uniformly, and separated by small interspaces. The chromatophores are much larger, and farther apart, and are superficial to the iridocytes, although sections show that their processes often pass down between adjacent iridocytes. The coloured chromatophores have less definite outlines than the black, and as a rule radiating processes are but indistinctly indicated in them. The external part of the coloured chromatophore consists of diffused yellow pigment, while in the centre the concentration of the pigment produces a deeper colour, varying from orange to red, as in the plaice and flounder. On the upper side of the fish the subcutaneous coloration elements are quite similar, but not so uniformly distributed; the iridocytes are larger, and the chromatophores not so symmetrical in shape.

The lower side of the normal flounder is uniformly opaque white, like chalk. Here in the more superficial part of the skin there is a uniform layer of iridocytes like those of the upper side, opaque and reflecting, but not very silvery or iridescent. Chromatophores are entirely absent. In the subcutaneous layer there is a continuous deposit of reflecting tissue, to which the whiteness of the skin is due, the superficial iridocytes not being sufficiently thick to make the skin so opaque.

We have shown by descriptions of the coloration elements in a number of species of symmetrical fishes such as mackerel, whiting, gurnard, *Cottus*, pipe-fishes, &c., that the general distribution of the elements is constant in all, the differences being in minute details.

In chemical and physical properties the substances contained in the coloration elements are as distinct as the elements are in appearance and form. The black chromatophores owe their colour to a melanin which is granular in its natural condition, is a nitrogenous body, and is very refractory towards reagents. The pigment of the coloured chromatophores is always a lipochrome, and the absorption bands of the various lipochromes obtained from the fishes examined do not differ to any great degree. The reflecting tissue was found always to consist of guanin in the pure state, not, as has often been stated, to a combination of guanin and calcium.

These investigations of the elements and substances of coloration were undertaken in order to find out what exactly took place when coloration was developed on the lower side of flounders in certain experiments carried on at the Plymouth Laboratory since the spring of 1890. The first experiment was not quite conclusive, although some pigment was found on the lower sides of the fish after an exposure to light of four months. The second experiment was quite conclusive. Four flounders were taken on September 17, 1890, from a number reared in the aquarium since the preceding May: they were five to six months old, and 5 to 8 cm. in length. They had been living under ordinary conditions, and were in all respects normal, having no colour on the lower sides. They were placed in the vessel above the mirror. On one of these, two faint specks of pigment were observed on April 26, 1891, one died on the following July 1, which showed no pigment, and one on September 26, 1891. The latter was 16·7 cm. long and showed only a little pigment on the posterior part of the operculum. At this time one of the two survivors had developed pigment all over the external regions of the lower side, and the other had a few small spots. The first of these two is still alive (March, 1893), being now three years old, and it is now pigmented over the whole of the lower side except small areas on the head and the base of the tail. A drawing showing its condition in November, 1891, was exhibited at the *soirée* of the Royal Society in 1892, and is laid before the Society with this paper. The other specimen died on July 4, 1892. It was then 25 cm. long and had a good deal of pigment in scattered spots on the lower side. This specimen had been exposed about one year and ten months. Several other experiments gave similar results.

The occurrence of abnormal coloration in pleuronectids is fully considered in the memoir; a large number of specimens are described, and it is shown that there is no evidence whatever that these specimens have been exposed to abnormal conditions. We conclude that these abnormalities are congenital and not acquired.

We conclude that exposure to light does actually cause the development of pigment in the form of normal chromatophores on the lower side of the flounder, and also causes the absorption of the argenteum to a great extent. We infer, in spite of the occurence of congenital abnormalities, that the exclusion of the light from the lower sides of flat fishes is the cause of the absence of pigment from that side in normal specimens. We think that the fact that the metamorphosis of the flounder takes place at first normally, in spite of the light coming from below and being shut off from above, is, in respect of the pigmentation, in favour of the inheritance of acquired characters. When the exposure is continued long enough, the change that has taken place in consequence of heredity is reversed, and pigment appears.

We consider that these investigations afford support to the view that the incidence of light is the reason why the upper and dorsal surface of animals is more strongly pigmented than the lower or ventral throughout the animal kingdom, and that the absence of light is the cause of the disappearance of pigment in many cave-inhabiting and subterranean animals.

Zoological Society, May 2.—Sir W. H. Flower, F.R.S., President, in the Chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of April; and called special attention to a young male Orang (*Simia satyrus*) brought home from Singapore, and presented by Thomas Workman, Esq.; a White-bellied Hedgehog (*Erinaceus albiventer*) from Somaliland, presented by H. W. Seton-Kerr; and a female Gibbon (*Hylobates muelleri*) brought home from North Borneo, and presented by Leicester P. Beaufort.—The Secretary laid on the table a list of the exact dates of the issue of the sheets of the Society's "Proceedings" from 1831 to 1859, concerning which information had lately been applied for.—Mr. P. L. Sclater, F.R.S., made some remarks on the occasional protrusion of the cloaca in the Vasa Parrot at certain seasons.—Mr. Sclater also read some further notes on the Monkeys of the genus *Cercopithecus*, and called special attention to *C. boutourlinii*, Giglioli, from Kaffa, Abyssinia, of which he had lately examined specimens in the Zoological Museum of Florence, and which he considered to be a perfectly valid species.—Mr. M. F. Woodward read a paper (the first of a series) entitled "Contributions to the Study of Mammalian Dentition." In the present communication the author treated of the dentition of the Macropodidæ, and described the presence of a number of vestigial incisors. He also showed that the tooth generally regarded as the successor to the fourth premolar was, in reality, a distinct tooth, and that the molars in this family of Marsupials belonged to the second dentition.—Mr. W. T. Blanford, F.R.S., read a description of two specimens of a Stag from Central Tibet, belonging to the Elaphine group, on which he proposed to found a new species, *Cervus thoroldi*. These specimens had been obtained by Dr. W. G. Thorold about 200 miles north-east of Lhasa, at an elevation of 13,500 feet above the sea-level, during his late adventurous journey through Tibet in company with Capt. Bauer.

Royal Microscopical Society, April 19.—A. D. Michael, President, in the Chair.—Mr. E. M. Nelson exhibited and described a mirror to be used instead of the camera lucida for the purpose of reflecting the real image from the microscope for drawing.—Mr. C. Rousselet exhibited a compressorium, the great advantage of which was that it enabled the object to be seen in every part of the field.—Mr. R. Macer exhibited and described a reversible compressorium which he thought might be useful.—Dr. G. P. Bate read a note on the illumination of diatoms by light reflected from the cover-glass in such a way as to produce a white ground illumination.—A letter from Captain Montgomery, describing the abundance of ticks in the coast lands of Natal, was read by Prof. Bell.—Mr. H. M. Bernard gave a *résumé* of his paper on the digestive processes in Arachnids.—Prof. Bell said that Mr. Bernard had made it appear probable that digestion was not confined to the digestive tract as usually understood, and in that case it might be that they were at the beginning of a series of observations which might throw a new light upon the processes of digestion.—The President said he had never worked much on these groups except amongst the Acarina. It was a curious thing that the distribution of the crystals referred to by Mr. Bernard was by no means the same in different families of the Acarina; in the majority of cases they lie outside the canal altogether, and are not found inside until they reach the hind gut. In the Gamasidæ they are poured into the cloaca. On the other hand there are families, such as the Tyroglyphidæ, where the crystals apparently never enter the hind gut at all, but are spread through the general body cavity. In the Oribatidæ a medium course seems to hold good, it being very difficult to ascertain where they enter the hind gut. Whilst in the Trombididæ they seem to enter in a definite channel down the centre of the back.—Mr. F. Chapman read a fourth paper on the Foraminifera of the Gault of Folkestone.—Prof. D'Arcy Thompson's paper on a Tænia from an Echidna was read by Prof. Bell.—Mr. C. H. Gill called attention to some pure cultivations of Diatoms which he exhibited.

EDINBURGH.

Royal Society, May 1.—Sir Douglas Maclagan, President, in the Chair.—A paper by Mr. John Aitken, on breath figures, was read. These figures are generally produced by breathing upon a piece of glass, on opposite sides of which two coins, or a coin and a piece of metal, have been placed, and have been oppositely electrified to high potentials. An image of the coin is thus developed. It appeared to the author that these figures depended on the presence of dust, or other impurities on the surface of the glass, and that similar effects might be produced by means of heat. The results of his experiments verified his conjecture and showed that dust has an effect on the formation of some kinds of breath figures.—A paper, communicated by Mr. H. B. Stocks, on some concretions from coal measures, and the fossil plants which they contain, was read. The concretions are found at Halifax, Yorkshire, and at Oldham, Lancashire. They are called "coal-balls" by the miners, and are found in a bed, belonging to the lower coal measures, above a stratum containing marine shells. The chief constituents are carbonate of lime and iron pyrites. The remains of plants which the balls contain are wonderfully preserved, every cell being well defined. Often the nodule is a mass of fosil wood, with a thin mineral coating. The author thinks that the bed has been formed in shallow water near the sea coast, the process of formation being similar to that now going on in the mangrove swamps of South America.—Lord Maclaren communicated a paper on the general eliminant of three equations of different degrees.

PARIS.

If, in equation 75 of the theory of adiabatic expansion, Maxwell had made $Q = \phi$ instead of $= \theta$, as he ought to have done, since Q is a function of $u+\xi$, $v+\eta$, $w+\zeta$, he would have obtained the formula

$$\frac{dp}{p} = \frac{5}{3}\frac{d\rho}{\rho}$$

where p is the pressure and ρ the density. This formula is not in accordance with experiment, but is a legitimate conclusion from the kinetic theory. Another error is pointed out in the theory of the conductivity of gases, where Maxwell's formula $K = \frac{5}{3\gamma}\nu$ ought to have been $K = \frac{5}{2\gamma}\nu$. For air, the experimental value is 56×10^{-6}, the calculated value from Maxwell's formula 54×10^{-6}, and the value calculated from the corrected formula 81×10^{-6}.—Shooting stars and fluctuations of latitude, by M. d'Abbadie.—On a new type of phosphorites, by M. REASON versus INSTINCT.

The Intelligence of Animals. By Charles William Purnell, Barrister-at-Law. (Christchurch and Dunedin, N.Z.: Whitcombe and Tombs, Limited, 1893.)

THIS little work has been written, the author states, in order to awaken public interest in the daily lives of the numerous animals which surround us, and to enforce the view that they are not mere lumps of animated clay, but creatures quickened by the fire of intelligence, and mentally as well as physically our brethren. The facts and arguments of modern writers on the subject have been condensed, and the results presented in a way calculated to interest the average reader, but always from the somewhat peculiar standpoint of the author. In his own words:—"The object of this work is, first, to prove that, among animals instinct, as distinguished from intelligence, is non-existent, that, in fact, it is a mere name; and, secondly, that the intelligence of the higher animals is essentially the same as our own."

After giving the definition of instinct from several writers, he proceeds to discuss the "Origin of Instincts," and he attributes it to hereditary habit, apparently unaware that the hereditary transmission of habits is either doubted or actually denied by a large number of naturalists. And he does not seem quite clear himself as to the meaning attached to the term, and to the necessity of excluding in any particular case in which it is alleged to exist, the possible influence of imitation, of physical or mental idiosyncrasies which are admittedly hereditary, and of natural or artificial selection. He considers handwriting to be sometimes hereditary, but does not apparently see that both imitation and inherited muscular or nervous peculiarities are almost sure to be present; while in the case of trained dogs and horses whose acquired habits are supposed to be hereditary, he clearly perceives that selection comes in, since he says:—"We know precisely how these habits have been acquired. The dogs and horses have been taught them by slow degrees; the animals displaying most aptitude for their acquisition have been carefully selected as breeders, until, finally, the habit has grown into the animal's mental constitution, and is perpetuated from parent to offspring." Further on, he tells us that when the beaver builds a lodge or constructs a dam, it does so by virtue of the inherited experiences of its forefathers. Of this there is no evidence whatever, while we are told that there is evidence of increased skill with age; so that instruction by, and imitation of, the older animals, with progressive improvement through experience, will account for all the facts.

A considerable portion of the work is occupied by facts and arguments directed against the doctrine that the actions of animals emanate from blind instinct, a doctrine which Mr. Purnell seems to think is almost universally held. When speaking of animals exhibiting joy, grief, love, hatred, pride, shame, revenge, or jealousy, he adds that we cannot conceive of an automaton being thus moved. And, after describing the dances of gnats and other insects, and the amusements of ants, he again declares that he cannot believe that these are "mindless beings no more responsible for their actions than the piston of a steam engine." Similar remarks are repeated again and again, as if the doctrine of the automatism of animals, instead of a philosopher's paradox, was the common belief of the educated world.

The author fully adopts the view that animals possess an æsthetic sense, admiring beauty of form and colour for its own sake; and he appears to be quite unaware that all the facts he adduces are explicable on the theory that the varied ornaments which we admire as being beautiful in themselves, may be to animals mere signs of the presence of desirable objects. Throughout his chapter on this subject he repeatedly states as facts, that animals *do* love beauty; that what delights our eyes delights their eyes also; that they admire the beauty of their fellow's brilliant colours; and as an indication that this is so, he urges that the colours of all animals form "harmonious combinations." The colours may be gaudy or odd, but they "harmonise well together," and "a true and perfect harmony does actually prevail in the colours of animals." This is often asserted, but how can it be proved? Do the glaring colours of the blue and yellow macaw form a harmonious combination? Or those of many of the barbets or chatterers? The colours, contemplated individually, are beautiful, owing to their purity and the delicacy of the glossy surface on which they are exhibited, often presenting the lustre of silk or satin, or the soft texture of velvet, while the rounded contours and delicate gradations of tint are also pleasing. Bu to assert that the combinations of colours are always, or even usually harmonious, in the sense in which we use the term as applied to combinations in a lady's dress or in the decorations of a room, seems to me to be completely opposed to the facts.

Notwithstanding these slight drawbacks, the work is full of interest. Almost every aspect of the subject is touched upon, and the writer often displays much originality in his discussions. We find very interesting chapters on the amusements of animals, on their individuality of character, on the education of their young, and on their language; and if he had confined his statement as to reason *versus* instinct, to the case of the higher animals, we might have been inclined to acknowledge that his view is the correct one. He does not, however, attempt to show how the theory of reason will apply to the acts of the larvæ of many insects, which seek special stations and construct special habitations for the pupæ, or of the perfect insects which lay up food for their young with the most admirable foresight and precautions. For these cases he falls back on hereditary habit; but it is difficult to see how this differs from the instinct which at the outset he denies the existence of.

Among the most original portions of the book is the chapter "On the Aspect which Man presents to the Lower Animals," and that on "The Animal View of the World." These are not so purely speculative as would appear at first sight, and some very good reasons are advanced for the conclusions arrived at. Mr. Purnell holds very strong views as to the rights of animals. He maintains that we are not justified in destroying them without adequate reasons. "The struggle for existence may force us to kill them for food or for our own self preservation; but the mere sportsman, and still less, he who destroys animals simply in order to display his skill in shooting, can show no moral sanction for his acts." And after a strong protest against cruelty to animals, he adds:—"Fortunately for us, the memory of the unutterable wrongs which dumb animals have sustained at man's hands cannot have been transmitted by them from generation to generation, or assuredly the entire Animal Kingdom would rise up in fierce rebellion against the common oppressor!"

On the whole, the book is very pleasingly and clearly written; it is divided into a number of short chapters each treating some well-defined aspect of the question; it contains examples of the best and most instructive facts illustrative of animal intelligence, and it is pervaded by a feeling of sympathy for the whole of animated nature. It is a pity that it is not issued in a more attractive form, the paper covers being hardly suited for such a book; but it is nevertheless well adapted as an introduction to the study of the subject, and will be especially interesting to those who think highly of the intelligence as opposed to the mere instincts of animals, and who are not afraid to recognise that even in their mental faculties and emotions the lower animals have much in common with ourselves.

ALFRED R. WALLACE.

OUR BOOK SHELF.

The Principles of Agriculture. By G. Fletcher. (Derby: The Central Educational Company, Ld.)

THIS little book is essentially a note-book of lectures given by the author, at the instance of the Technical Education Committee of the Derbyshire County Council, to schoolmasters and others intending to become teachers of agriculture. The syllabus covers the ground usually gone over in such a course, the arrangement of subjects being somewhat similar to that adopted by Fream in his well-known "Elements." The book contains, in a small space, a good deal of information, and, at the same time, indicates points with which the student should make himself acquainted, but which could not be given in detail in a work of this kind. It seems to be carefully written, and, on the whole, very free from errors; it will, no doubt, be a useful guide both to teachers and students of agriculture.

Au Bord de la Mer: Géologie, Faune, et Flore des Côtes de France. Par le Dr. E. L. Trouessart. (Paris: J. B. Baillière et Fils, 1893.)

IT often happens that people who go to the seaside for a holiday would be glad, if they could, to learn something about the scientific meaning of the objects by which they are surrounded. They have neither time nor inclination for the study of elaborate works, and as a rule there is not much to be gained by the perusal of local guide-books. Persons of this class in France will find exactly what they want in the present volume. The author gives first a sketch of the geology of the French coasts from Dunkirk to Biarritz, then deals with such marine plants as are likely to interest the reader, and finally presents an account of marine animals. The style is clear and unpretending, and the text is illustrated with no fewer than 149 figures.

LETTERS TO THE EDITOR.

The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*]

Mr. H. O. Forbes's Discoveries in the Chatham Islands.

IN a recent letter in NATURE (vol. xlviii. p. 27), under the above heading, Mr. Wallace has done me the honour to make some observations on the conclusions I have arrived at on other discoveries I have made in the Chatham Islands, and on the evidence adduced in my paper read before the Royal Geographical Society on March 12 last, *i.e.*, that an Antarctic continent—which I may name Antipodea—is necessary to explain the distribution of life in the southern hemisphere. Mr. Wallace says, "It is this tremendous hypothesis which appears to me to be not only quite unnecessary to explain the facts, but also to be inadequate to explain them. If one thing more than another is clear, it is that these comparatively small flightless birds were developed, as such, in or near to the islands where they are now found, since they could not possibly have arisen on any extensive land inhabited by carnivorous mammals and reptiles, and, if introduced into such a country could not long survive." If by this Mr. Wallace means that only the flightlessness of these birds, apart from their general structure as members of the genus *Aphanapteryx*, arose in or near the islands where they now are, he still leaves the, to me, greater difficulty unexplained how two so closely related species of the same genus should have arisen in regions separated by nearly one half of the circumference of the globe. For it has to be remembered that *Aphanapteryx* belongs to the *Ocydromine* group of the Rails, which is quite unknown in the northern hemisphere, and, therefore, to have reached "Lemuria" (the ancient land of which Madagascar, Mauritius, Bourbon, Rodriguez, and the Seychelles, are the fragments) the genus must have arisen independently in both regions where its species are now found, or it spread from one or the other centre, or from some common land *by flight*. Mr. Wallace has himself pointed out that to explain the presence of the flightless *Notornis* and *Ocydromus* in two groups of islands in the New Zealand region requires a land connection, for it has been hitherto considered an axiom of geographical distribution that the regions inhabited by the same genus or species have been continuous, or have been, at all events, such as to afford possibilities of migration from one to another. If *Aphanapteryx* could have spread from the Chatham Islands to Mauritius by flight, surely *Notornis* and *Ocydromus* did not require a land connection to reach from New Zealand to the nearer outlying islands, for they may equally have lost the use of their wings only after they reached their present homes.

When Mr. Wallace asserts that these birds "could not possibly have arisen on any extensive land inhabited by carnivorous mammals and reptiles," he affirms what does not really appear to me to carry with it conviction without more proof. Rails belong to a family of birds that have become of world-wide distribution, not improbably because of the habits of its members enabling them to escape destruction. They are better runners than flyers; they are water and marsh-loving birds, many of them living in reed and rush brakes, and the dense vegetation surrounding marshes, amid which pursuit is difficult or impossible. I was much struck when in the Chatham Islands by observing how the habits of the small *Ortygometra tabuensis* protected it. The upland districts of Wharekauri are covered by a very dense rush-like vegetation—the *terahina* of the natives—in which this little Rail lives. We hunted over acres and acres of country with the aid of a dog well trained to pursue and catch this species, but only after two days did we succeed in securing a specimen. We could see that the dog disturbed plenty of birds, but so rapidly could they make their way through the *terahina* that they all escaped, for they never took to flight. The *Cabalus modestus* is a nocturnal bird hiding securely in hollow trees and grass thickets all day. *Notornis* inhabited, and perhaps still inhabits, the dense scrub of the south-western portion of New Zealand, and could have there escaped the severest persecution of carnivorous animals and reptiles. But even if *Aphanapteryx* had been subjected to the incessant and successful attacks of such enemies, its extinction, whether early or late, would depend on the numbers in which it was reproduced. Many species of animals, it is needless to point out, such as rats and mice, are ceaselessly persecuted by enemies, and yet survive, and from time to time spread over vast areas. The lemming, notwithstanding that thousands yearly perish by their own act, and from the attacks of enemies during their migration, has not become extinct. Nor can I see that 2000 miles is such an "enormous extent of land" for a migration to extend over, even in face of carnivorous mammals and reptiles. It is at least not so great as the distance covered during the migration of the South American tapirs from Central Europe *via* Behring's Straits to Brazil, the route supposed by Mr. Wallace to have been taken by the ancestors of these interesting animals.

Mr. Wallace asks, "What difficulty is there in the same or closely allied species of this widespread group finding their way at some remote epoch to Mauritius and the Chatham Islands, and from similar causes in both islands, losing their power of flight while retaining their general similarity of structure?" I must reply, none; and then ask in turn, from where did they find their way? which is the point under discussion. I am constrained to believe that they came from an extensive land, capable of supporting large numbers of them, which must have been continuous with (as indicated by other evidence) or approaching close to both regions, otherwise we have to believe that this strictly Notogæan group has "found its way" across half the globe, or has arisen independently in both regions from different sections of the family—an occurrence which we have no evidence to warrant our believing has ever taken place.

I am unable to speak for the present opinions of Prof. Newton or his brother; but I know of no additional evidence that has come to light that is likely to have modified their well-considered opinion of a few years ago. On the contrary, it seems to me confirmatory of their views.

I beg, however, to protest against the implication that I have invoked this "tremendous hypothesis" to account for the distribution of the *Aphanapteryx* and *Fulica* I discovered. I have given prominence no doubt to the valuable evidence their presence contributes, additional only, however, to the numerous other facts I have adduced in my paper before the Royal Geographical Society, in support of the theory that a land of extensive dimensions—not isolated islands only as Mr. Wallace agrees to—existed in the southern seas, in order to explain the distribution of plants and animals, *unknown in the northern side of the equator*, in regions so distant as South America, Australia, New Zealand, and "Lemuria." I have, in my own opinion, adduced no more cogent facts pointing in this direction than those published by the late Prof. W. K. Parker, showing plainly the common ancestry existing between the Notogæan (Gymnorhine) crows of Australia, and the Deudrocolaptine birds of South America. Their common progenitor must have occupied some *southern* land connected with both Australia and South America.

I might adduce still other weighty examples from the domain of ornithology, tending to support my opinion, which have been kindly communicated to me by Dr. Bowdler Sharpe, but I forbear now, as I understand that this will form the subject of the second lecture of the course he is now delivering on Thursday afternoons at the Royal Institution.

104, Philbeach Gardens, May 20. HENRY O. FORBES.

Phagocytes of Green Oysters.

IN your issue of May 4 you refer in a note to a suggestion made by my friend and former pupil, Dr. Paul Pelseneer that the green amœboid cells described by me as occurring on the surface of the gills of green oysters are to be interpreted as out-wandered phagocytes. It is, I think, only right to point out that Dr. Pelseneer (as he is careful to explain in the note published by him) has made no new observations on the matter, and merely professes to give an interpretation of the facts which I described in 1886 in the *Quart. Journ. Micr. Sci.* in my article on green oysters. I there described and figured large granular cells occurring in and upon the epithelium of the gill-filaments and regarding them as epithelial secretion-cells attributed to them the active part in the elimination of the blue pigment "marennin" taken in by the oyster in its food—the diatom *Navicula ostrearia*. At that time the general doctrine of "phagocytosis" had not been so fully developed as it is now seven years later. But I may say that already in 1887 one of my pupils (Mr. Blundstone) had established to my satisfaction the existence of extensive out-wandering of phagocytes through the surface epithelium of *Anodon* in various regions of the body, and that I was very soon led by the accumulating evidence of a similar kind (*e.g.* Durham's observations on star-fishes) to adopt the view that the large "secretion-cells" discovered by me both in the epithelium of the oyster's gill and freely moving on its surface, were out-wandered phagocytes. I have taught this view in my lectures, and have made some further observations (two years ago) on similar out-wandering phagocytes in other Lamellibranchs. The subject is one well worthy of minute study, phagocytosis in Mollusca being as yet an unexplored ground likely to yield results of great physiological importance. E. RAY LANKESTER.

Oxford, May 7.

The Conjoint Board's Medical Biology.

THE pertinent remarks of L. C. M. (NATURE, vol. xlviii., p. 29), and G. B. H. (vol. xlvii., p. 530), respecting the course of elementary biology prescribed by the Conjoint Board, expresses, I think, the feelings of most biologists.

Either it is desirable, or not, that previous to entering upon a course of purely medical studies the student should have a training in elementary biology. The Board have decided in the affirmative, and have prescribed a course as amusing as it is absurd. It demands a practical acquaintance with the structure of certain protozoa, *Hydra*, the leech, two or three parasitic worms, a scrappy knowledge of botany, and a few generalities. The insecta, crustacea, mollusca, and the whole of the vertebrata, are entirely omitted in the practical work. Under such circumstances it is almost ridiculous to attempt to impart any true knowledge of biology, in fact it is quite impossible to do so, for in the absence of such types as the crayfish, dogfish or cod, very many important morphological facts cannot be illustrated.

It would be interesting to learn the constitution of the committee who have drawn up this inexplicable syllabus. One really cannot for a moment suppose that they are acquainted with the scope and aim of present-day biological teaching, but from hazy memories of their student days, and an acquaintance with *Tænia*, *Ascaris*, and the leech, have drawn up the present course. The examination, I should remark, is in *perfect keeping* with the syllabus.

The important morphological facts to be gained by a dissection of the leech are probably best known to the Board.

It is sincerely to be hoped that the matter may not be allowed to rest here, but that some steps will be taken to impress upon the Board the utter absurdity of their present syllabus and mode and standard of examination, and the need for a recognized course in both zoology and botany.

WALTER E. COLLINGE.

Mason College, Birmingham, May 15.

Vectors *versus* Quaternions.

AS in recent numbers of NATURE my views on analysis have been quoted, and not very correctly, I ask for space to state them more explicitly. I see truth in the quaternion analysis and in the vector analysis; but I believe that neither the one nor the other, nor the two combined, contain the whole truth. The vector is an important idea, and the quaternion is an important idea, but there are in physical science many other important ideas which call for a more direct notation. To avoid any narrow hypothesis I denominated my first paper "Principles of the Algebra of Physics"; but in the notice which NATURE honoured it with it was printed as "Principles of the Algebra of Vectors." The title I gave it indicates briefly my position. I have been looking at analysis from the point of view of the physicist, and one of my guiding ideas has been that the fundamental rules of analysis, instead of being assumed as so many arbitrary rules of operation, should be grounded on the fundamental laws of physics.

What is the greatest want of the physicist of the present day? It is a generalised analysis which shall not contradict the Cartesian analysis, but be a logical generalisation of it, which shall include and harmonise such methods as the Double Algebra of Argand, Cauchy, and De Morgan (an excellent presentation of which has recently been published by Mr. Hayward), the method of Determinants, the Matrices of Cayley, the

Quaternions of Hamilton and Tait, the *Ausdehnungslehre* of Grassmann, the vector analysis of Gibbs and Heaviside. It is this problem of how to harmonise, unify, generalise, and extend that I have been studying. Analysts and physicists dislike Mr. McAulay's idea of an independent plant; they prefer to cultivate the old tree venerable with the growth of ages.

After studying impartially all the writers at my command I came to the conclusion that the analysis of vectors is complementary to the analysis of versors, and that the fundamentel rules for the former are :—

$$i^2 = + \qquad j^2 = + \qquad k^2 = + \qquad (1)$$
$$ij = -ji \qquad jk = -kj \qquad ik = -ki \qquad (2)$$
$$ij = k \qquad jk = i \qquad ki = j \qquad (3);$$

whereas for the latter they are :—

$$i^{\frac{\pi}{2}} i^{\frac{\pi}{2}} = - \qquad j^{\frac{\pi}{2}} j^{\frac{\pi}{2}} = - \qquad k^{\frac{\pi}{2}} k^{\frac{\pi}{2}} = - \qquad (4)$$
$$i^{\frac{\pi}{2}} j^{\frac{\pi}{2}} = - j^{\frac{\pi}{2}} i^{\frac{\pi}{2}} \quad k^{\frac{\pi}{2}} j^{\frac{\pi}{2}} = - j^{\frac{\pi}{2}} k^{\frac{\pi}{2}} \quad i^{\frac{\pi}{2}} k^{\frac{\pi}{2}} = - k^{\frac{\pi}{2}} i^{\frac{\pi}{2}} \quad (5)$$
$$i^{\frac{\pi}{2}} j^{\frac{\pi}{2}} = - k^{\frac{\pi}{2}} \qquad j^{\frac{\pi}{2}} k^{\frac{\pi}{2}} = - i^{\frac{\pi}{2}} \qquad k^{\frac{\pi}{2}} i^{\frac{\pi}{2}} = - j^{\frac{\pi}{2}} \qquad (6)$$

It follows that in the manipulation of the products of vectors, the distributive rule applies but not the associative; while in the products of versors both apply. These fundamental rules for vectors are based on physical considerations, the principal one of which is that the square of a vector is essentially positive, whereas, according to quaternionists, it is essentially negative. My view agrees with that principle of analysis which considers the cosine in the first and fourth quadrants to be positive; to make it negative produces confusion and error. These principles harmonise with those of Gibbs and Heaviside; and in the memoir quoted I have carried them out to their logical development. It is this development which Prof. Knott characterises as "a pseudo-quaternionic system of vector algebra, which is non-associative in its products." I see no worthy aim in being canny about the matter; my sole aim was to develop the system so that its truth or falsity might the more readily appear. At the end of his article Prof. Knott admits that the *assumption* that the square of a unit vector is positive unity leads to an algebra which is essentially different from the algebra of quaternions. As regards the fundamental principle being an assumption, I refer him to that same chapter of "Kelland and Tait" which he quotes, where he will find, italics and all:—"We retain what Sir Wm. Hamilton terms the *associative laws of multiplication*: the law which assumes that it is indifferent in what way operations are grouped, provided the order be not changed; the law which makes it indifferent whether we consider abc to be $a \times bc$ or $ab \times c$. This law is *assumed* to be applicable to multiplication in its new aspect (for example that $ijk = ij.k$) and being assumed it limits the science to certain boundaries, and, along with other assumed laws, furnishes the key to the interpretation of results. The law is by no means a necessary law. Some new forms of the science may possibly modify it hereafter. In the meantime the assumption of the law fixes the limits of the science." Here an authoritative expounder places the quaternion algebra on precisely the same footing that Dr. Knott places the "pseudo-quaternionic;" and he even predicts that in the course of time such a complementary algebra will be developed. It is incumbent on a critic, having admitted the logical development, to show that the assumptions are absurd, or correspond to nothing in physical science; instead of which he informs us that he is appalled by the complexity, but nevertheless he feels sure that it contains nothing new. As regards newness I invite his attention to pr. 93 of the "Principles," where I have investigated the rules for the several partial products of any number of vectors in space of not more than four dimensions (and they may be easily extended to space of higher dimensions). These consist of certain rules of reduction which are to be taken along with the rule of signs of determinants, thus embracing determinants and Grassmann's combinatory products in the general theory of products of vectors. He will also find there some reasons for believing that the triad of rules No. 3 are very different in nature from the other two triads, Nos. 1 and 2. It is possible to get along without No. 3.

That vectors should be treated vectorially, and versors versorially, and rotors rotorially, is neither nonsense nor a truism. It is an important maxim, and of growing importance in these days. Violation of it has produced the fundamental weakness of Hamilton's analysis. In a more recent paper I have published the generalisations for space of the exponential, binomial, multinomial, and other fundamental theorems of analysis, and I show that it was from treating versors vectorially that Hamilton failed to discover them.

Prof. Knott defines a quaternion as the quotient of two vectors. Why choose the quotient; is not the product always the simpler idea? But further on vectors are identified with quadrantal quaternions, from which it follows that a quaternion is the quotient of two quadrantal quaternions. I have devoted some attention to logic; but I fail to extract any meaning out of this implicit definition.

Prof. Knott informs the reader that whereas Heaviside and myself find that $\nabla^2 u = d^2u/dx^2 + d^2u/dy^2 + d^2u/dz^2$ the real $\nabla^2 u$ is minus that quantity; but he does not explain why Prof. Tait prefers the unreal $\nabla^2 u$ in his "Treatise on Natural Philosophy." A scientific critic would, instead of using exclamation points, proceed to show that in every case $\nabla(\nabla\omega) = (\nabla\nabla)\omega$. If that can be proved, not from any fancied properties of italic letters, but from physical considerations, then I shall readily admit that ∇ behaves as a versor rather than a vector. The *onus probandi* lies on the minus men.

Austin, Texas, May 6. Alexander Macfarlane.

An Atmospheric Phenomenon in the North China Sea.

During a recent wintry cruise in H.M.S. *Caroline* in the North China Sea, a curious phenomenon was seen which may be of interest to your readers. The ship was on passage between Shanghai and the western entrance of the famous inland sea of Japan. On 24th February, at 10 p.m., when in latitude 32° 58′ N., longitude 126° 33′ E., which, on reference to the map, will be seen to be sixteen to seventeen miles south of Quelpart island (south of the Korean peninsula) some unusual lights were reported by the officer of the watch between the ship and Mount Auckland, a mountain 6,000 feet high. It was a windy, cold, moonlight night. My first impression was that they were either some fires on shore, apparently higher from the horizon than a ship's masthead, or some junk's "flare up" lights raised by mirage. To the naked eye they appeared sometimes as a mass; at others, spread out in an irregular line, and, being globular in form, they resembled Chinese lanterns festooned between the masts of a lofty vessel. They bore north (magnetic), and remained on that bearing until lost sight of about midnight. As the ship was passing the land to the eastward at the rate of seven knots an hour, it soon became obvious that the lights were not on the land, though observed with the mountain behind them.

On the following night, February 25th, about the same time, 10 p.m., the ship having cleared Port Hamilton, was steering east, on the parallel of 34°, when these curious lights were again observed on the same bearing, at an altitude of 3° or 4° above the horizon. It was a clear, still, moonlight night, and cold. On this occasion there was no land in sight on a north bearing when the lights were first observed, but soon afterwards a small islet was passed, which for the time eclipsed the lights. As the ship steamed on at a rate of seven knots an hour, the lights maintained a constant bearing (magnetic) of N. 2° W., as if carried by some vessel travelling in the same direction and at the same speed. The globes of fire altered in their formation as on the previous night, now in a massed group, with an outlying light away to the right, then the isolated one would disappear, and the others would take the form of a crescent or diamond, or hang festoon-fashion in a curved line. A clear reflection or glare could be seen on the horizon beneath the lights. Through a telescope the globes appeared to be of a reddish colour, and to emit a thin smoke.

I watched them for several hours, and could distinguish no perceptible alteration in their bearing or altitude, the changes occurring only in their relative formation, but each light maintained its oval, globular form.

They remained in sight from 10 p.m. until daylight (about 5.30 a.m.). When lost sight of the bearing was one or two points to the westward of north. At daylight land 1300 feet high was seen to the north and north-north-west, distant fifty miles, the mirage being extraordinary.

Thus, these lights were seen first in longitude 126° 33′ E., and last in longitude 128° 29′ E. At first the land was behind them, but during the greater part of the distance run it was forty-five or fifty miles away to the north; and the bearing of the lights for at least three-fourths of the distance did not change.

On arrival at Kobé I read in a daily paper that the "Unknown light of Japan" had, as was customary at this season of the year when the weather is very cold, stormy, and clear, been observed by fishermen in the Shimbara Gulf and Japanese waters. The article went on to say that these lights were referred to in native school-books, and attributed to electrical phenomena. On mentioning the matter, however, to the leading Europeans in Yokohama and Tokio, they appeared to have no knowledge of the matter.

Captain Castle, of H.M.S. *Leander*, informed me that, not long ago, the officers of his ship saw lights in the same locality which they thought at first were caused by a ship on fire. The course of the vessel was altered at once with a view of rendering assistance, but finding that the lights increased their altitude as he approached, he attributed them to some volcanic disturbance, and being pressed for time, resumed his course.

The background of high land seen on the first night dispels all idea of these extraordinary lights being due to a distant volcano. The uniformity of the bearing renders the theory of their being fires on the shore most improbable. I am inclined to the belief that they were something in the nature of St. Elmo's fires. It is probable that there are travellers among the readers of your interesting journal who have seen or heard of this phenomenon, and will be able to describe its origin and the atmospheric conditions necessary for its appearance.

CHAS. J. NORCOCK.

H.M.S. *Caroline*, Hongkong, April 10.

The Greatest Rainfall in Twenty-four Hours.

IN NATURE, May 4, Mr. Clement Wragge, of Brisbane, confidently asserts that Queensland has beaten the world's record in the extraordinary amount recorded on February 3, viz., 35·7 inches. I am sorry to have to take away such an unenviable palm from Queensland, by recalling a fact well known to every Indian meteorologist that the highest record extant belongs to Chirapunji, in the Khasia hills, where on June 14, 1876, 40·8 inches were recorded in the twenty-four hours. Not only so, but on the 12th 30 inches fell, and in the four days, from the 12th to the 15th inclusive, as much as 102 inches. Of course the effects were not so disastrous in this case, as indeed such a state of things is little removed from the normal at Chira in the early part of June, but I have a very clear recollection of it as I was at Chirapunji on the 12th and 13th, and not far from it on the memorable 14th.

The conditions which have occurred in Queensland and the North Island of New Zealand during the last six months have been a remarkable example of persistent abnormals, and though the total number of rational causes may still be wanting to explain everything, one or two were evidently in operation when I was there from October to January, and I am confident that from the empirical law of persistency, coupled with a few rational inferences, a forecast of impending floods could have been made and can be made for the future, much in the same way as the general character of the monsoon can be foretold in India.

May 13. E. DOUGLAS ARCHIBALD.

A Dust-whirl or (?) Tornado.

IN NATURE (vol. xl. p. 174) you kindly allowed me to describe a dust-whirl seen to originate on a heated dust-covered highway. The phenomenon has just been repeated under much similar circumstances, only in this instance the column of dust after oscillating to and fro on the highway for about half a minute, moved rapidly away in a curvilinear path in a northerly direction, the lower end of the whirl catching up loose material in its track where it touched the ground, which it did at intervals of from ten to fifteen yards, carrying the strawy litter from a strawberry bed upwards of 50 yards in the air. It appeared to dissipate into the upper air when crossing a meadow some 300 yards from its place of origin. The characteristic "swish" of the rushing air was very marked, and the four motions common to all tornadoes (see Lieut. Finley's "Character of Six Hundred Tornadoes"), viz. whirling from right to left, progressive motion to the north, a curvilinear track, and the dipping up and down, were all distinctly traced. The question therefore, naturally arises—Can these dust-whirls be tornadoes in miniature?

Conditions at the time of the occurrence:—Date, Thursday, May 11, 1893; time, 11 a.m. Corrected barometer, 30.327 (falling slightly). Dry bulb, 66°.5; wet, 51°.8 = rel. hum. 38 per cent. Wind, south; force, 1. Some upper cirrus radiating from north-east, and drifting slowly from north-west, showing top and bottom arcs of halo at 10 a.m. Black bulb *in vacuo* 128°.2; weather very warm and dry.

Driffield, May 11. J. LOVEL.

What becomes of the Aphis in the Winter?

I HAVE spent many weeks this spring closely observing the budding trees, with the object of discovering in what condition of life the aphis spends the winter; as the result of my observations, which were made under the microscope, I believe that the aphidæ during the autumn (or as many of them as have reached the state of reproduction) attach themselves to the stem of the tree, with their young inside them, in much the same way as the female members of the closely-allied family coccidæ do. In course of time the mother-aphis becomes simply a dried skin serving as a protection to the young. When the warm days of spring come these are developed and easily make their way through the skin and crawl on to the young leaves, there to begin their work of sucking and reproduction.

T. A. SHARPE.

Soot-figures on Ceilings.

MAY I suggest a distinct, if not an alternative cause for Prof. E. B. Poulton's soot figures in NATURE, April 27th? The ceiling plaster is very porous, except where it is in contact with the joists, etc. At such points very little deposit occurs compared with the spaces where the hot air is vigorously diffusing through into the cold space above. I suggest this because I am very familiar with a large ceiling where the rafters are thus picked out in light shades. Even the laths are picked out, but less distinctly. The main bolts likewise show dark, as in Prof. Poulton's sketch, as if there were an air-space by them. There is no perceptible difference in the figures near the central chandelier from those in the corners remotest from heating causes. The bombarding pattern is often very well shown where super-heated water pipes run along a white-washed wall. The effect of every little break, even a nail in the wall, is most striking.

J. EDMUND CLARK.

A Difficulty in Weismannism Resolved.

IN my letter of the 1st inst. an omission of parentheses and quotation marks, which I omitted to note on the proof, alters the sense of the paragraph with quotations from the "Germ Plasm," pp. 434–5. It should be as follows:—"The note runs thus: 'Compare Marcus Hartog, NATURE, vol. xliv. p. 102,' (the reference omits my letter of Oct. 31, 1891). 'The deductions made by this author are logically correct but are no longer justifiable, since I myself have gained further insight into the problems concerned.'" The absence of the inverted commas disguises this recognition by Weismann of the validity of my objections, and of the consequent change in his own views.

Cork, May 15. MARCUS HARTOG.

NOTES.

THE Hon. Ralph Abercromby has given to the Royal Society of New South Wales the sum of £100, which is to be offered as prizes with the object of bringing about exhaustive studies of certain features of Australian weather. So far only one feature has been selected, and a prize of £25 is now offered for an exhaustive study of the well-known "Southerly Burster." It is understood that no essay which does not deal fully with the following points will be considered:—(1) The motions of the various strata of clouds for some hours preceding, at the time of, and following the "burster;" (2) the weather conditions which lead up to and follow the "burster," with weather charts of Australia for the day of occurrence and the following day; (3) the general conditions which modify the character of the "burster;" (4) The area of the "burster" and its track; (5) barograph traces showing the changes of pressure during the "burster;" (6) the direction and character of wind preceding it; (7) the relation of "bursters" to rainfall. The essay must not exceed 50 pages of foolscap, and must be sent in not later than March 31, 1894. It must embody studies of several "bursters," and must be chiefly the result of original research of the author, but authors are not debarred from making use of any available information, published or otherwise, on the subject. A photograph of each "burster" described, giving a characteristic view of the cloud roll should, if possible, be sent with the essay.

DR. N. WILLS has been appointed ordinary professor of botany at the University and Director of the Botanic Gardens at Christiania.

A MOST disastrous landslip occurred on the night of May 18, at Vaerdalen, in the district of North Trondhjem. Vaerdalen is a straggling country town with about 6000 inhabitants, and is an agricultural centre. The landslip occurred in the outskirts of the town, where there are a number of houses occupied by peasants, each farming his own land. The subsidence was so sudden and severe that between thirty and forty of these farmhouses fell instantaneously in ruins, leaving scarcely a wall standing. Twenty-two of the demolished houses were of considerable size, and many people were asleep in them when the catastrophe happened. The number of victims is estimated at close upon one hundred. The loss of property is very great. According to a Reuter's telegram, from which we learn these details, the most fruitful part of the Vaerdals-Elv Valley lies under a mass of mud and slime, and it is feared that further landslips will occur.

DURING the past week the day temperatures over the British Islands have been mostly below 70° in the south and west, while in the north of Scotland several of the maximum readings have not exceeded 55°. On the 18th inst. rainy weather had become general, with thunderstorms in many places; on that morning some heavy falls were measured, Ardrossan reporting 0·75 inch, York 0·74 inch, Loughborough 1·60 inch, and Jersey 0·91 inch, while on the following days large amounts were measured in various parts of Ireland. A small depression lying off the south-east coast of England on Sunday, the 21st inst., also brought over half an inch of rain to that part of the country, while in the early part of the present week the distribution of atmospheric pressure was favourable for further falls over the country generally. The *Weekly Weather Report* of the 20th inst. showed that the excess of temperature for that week ranged from 4° in the northern districts to 6° in most parts of England, that the rainfall was rather less than the mean in the north of Scotland, and equalled, or exceeded it, in all other districts. From the beginning of the year there is a deficit in all districts, amounting to 5·3 inches in the west of Scotland. Bright sunshine was below the average amount in all districts.

A PAPER on "Wreck-raising in the River Thames" was read by Mr. C. J. More, engineer to the Thames Conservators, at the meeting of the Institution of Civil Engineers on May 16. Mr. More mentioned that during the past eleven years seventy-four steamers of 55,758 tons register, fifty-four sailing vessels of 9,128 tons, and three hundred and one barges of 11,956 tons, being a total of 76,842 tons register of shipping, had been raised by the Conservancy lighters.

THE death of the well-known engineer, Mr. E. A. Cowper, is announced. He was in his seventy-fourth year. Mr. Cowper displayed much ingenuity as an inventor, and was connected with many technical institutions, including the Institution of Civil Engineers, of the council of which he was a member, the Institution of Mechanical Engineers, of which he was president in 1880–81, and the Iron and Steel Institute.

A MAP of the smokes of Paris has been recently prepared by M. Foubert, of the Tour Saint Jacques. The idea is to note the position of the principal factory chimneys, to observe during the day the emission of smoke, then to indicate on the map, for each chimney, by means of circles of various sizes and tints, the extent of the nuisance. There are obvious defects (as M. Delahaye points out in the *Revue Industrielle*) in such a mode of representation. Thus no account is taken of smoke from the environs, which materially affects Parisian air. The black particles emitted from factory chimneys in some cases sink rapidly, but in others are long maintained in suspension. Then there is the large emission of smoke from private dwellings. M. Delahaye manifests some partiality for city smoke; he remarks on its antiseptic properties in time of epidemic, and on the screening action, whereby it prevents losses of heat by radiation.

AT the meeting of the Linnean Society of New South Wales on March 29 Prof. David contributed a note on the discovery by him of the mineral sphene *in situ* in granite at the Bathurst waterworks. In the latest edition of his work on the minerals of New South Wales, Prof. Liversidge has described a single well-formed crystal of sphene from New South Wales, but the exact locality from which it came is uncertain. In the Bathurst granite crystals of sphene are abundant, and vary in size from $\frac{1}{30}$th up to $\frac{1}{4}$ inch in longest diameter. The crystals are of a very deep brown colour, and feebly translucent. In chemical composition the mineral is a compound of silica, lime, and titanic acid.

M. VERNER has a note in the *Journal de Physique* on an explanation of the rotation of the plane of polarisation in a magnetic field based on de Reusch's experiments. From the experimental fact that a pile of birefringent plates in which the principal sections are arranged helically rotates the plane of polarisation, it follows that a birefringent body turning about a direction perpendicular to its optical axis will rotate the plane of polarisation of a ray which traverses it parallel to the axis about which it is turning. For if the body is supposed divided into a series of plates by planes perpendicular to the axis of rotation, while the light is traversing the first plate the body will have turned through an angle, and therefore the principal plane of the second plate will be inclined to the direction which the principal plane of the first plate occupied when the light passed through it. Thus if the speed of rotation is comparable with the velocity of light the plane of polarisation will be rotated. This being so, the author makes the hypothesis that, in a magnetic field, at any given moment, the magnetic stress at a point on a line of force is only exerted in a certain azimuth normal to the direction of the line, and that the plane containing the portion of the line of force, and the direction of this stress, turns about the direction of the line of force with a velocity proportional to the intensity of the magnetic field at the point. Hence, when a substance such as carbon bisulphide is placed in a magnetic field, this magnetic stress, transversal to the lines of force, causes the body to become birefringent, with its principal plane coinciding with the direction of this stress, and if, as is supposed, this direction rotates, the principal plane will rotate, and the substance will exhibit magnetic rotatory power. The above explanation accounts for the fact that the direction of the rotation is independent of the direction in which the ray of light traverses the magnetic field.

THE extensive researches of Pellat have shown the considerable change produced in the value of the difference of potential between the layers of air covering two metals in contact by the least chemical or mechanical alteration of the surfaces. In the *Journal de Physique* for May M. Gouré de Villemontée describes his attempts to prepare metallic surfaces which shall give a constant difference. For this purpose he deposits the metal by electrolysis on plates of copper, or on small lead shot, and has studied deposits of iron, nickel, zinc, and copper made from solutions of different salts, at temperatures ranging from 10° to 40° C., and with varying current densities. The method adopted to determine the difference of potential consists in forming, with the two plates which are being experimented on, a condenser having its plates joined by a wire in which an opposing electromotive force could be produced. The conclusions the author arrives at are, that the difference of potential at the point of contact of two electrolytically deposited layers of the same metal is independent of the density of the current, and of the temperature and composition of the solution used in forming the deposit. He also finds that two deposits prepared at different times are identical, and give no contact difference of potential even when as much as a month elapses between their preparation.

AN improved apparatus for exhibiting the phenomena of gaseous diffusion is described by Prof. V. Dvorák in the *Zeitschrift für Physikalischen Unterricht*. A porous pot such as is used for galvanic batteries, but in a fresh and clean condition, is well closed by a greased cork through which pass a bent glass rod and a glass tube. The tube is attached to a narrow india-rubber tube leading to a horizontal capillary glass tube ending in a small cup. The capillary tube contains a drop of alcohol which serves as an indicator. The earthenware pot is placed in an inverted position, the glass rod serving as a handle. A tray of sulphuric acid containing pieces of zinc is placed under an inverted beaker, which collects the hydrogen evolved and is then slipped over the porous pot. The gas, entering the pot by diffusion more rapidly than the air leaves it, drives the drop of alcohol quickly outward. A similar effect is produced by coal-gas, and the opposite effect by carbonic acid or ether. This may also be strikingly shown by lightly breathing into the beaker and applying it to the porous pot, when the displacement of the drop will indicates the presence of the heavier gas in the breath.

IT is a common belief in India that, if a cobra is killed, and the remains are left in a bungalow, others of the species will be attracted to the spot. A correspondent of the *Pioneer Mail* records an incident which appears to indicate, as he says, that there is some truth in this theory. About nine months ago Col. Ilderton killed a very large cobra in the compound of his bungalow at Dinapore, and had its skin stuffed and set up by a native mochee. Since then the compound has been infested with these snakes, and no less than eight full-grown cobras, measuring from 4 ft. 8 in. to 5 ft. 4 in., have been killed there; one of which was sitting up, with its hood extended, contemplating the house where the remains of its preserved friend were. It is a curious fact that every snake when found was making in the direction of the bungalow, and most of them showed fight when tackled. The last two were within a few feet of each other, when Col. Ilderton killed them with a stick, and were advancing up the carriage drive together. No cobras have been seen in other parts of the station.

MR. HOPE HUNTER, writing in the *Journal of the Royal Agricultural and Commercial Society of British Guiana* on gold in that colony, says that the explorer has no reason to penetrate further than two hundred miles inland for the discovery of new and extensive gold fields, but that, if he desired to extend research further, the debatable land between the colony and the Brazilian possessions in the south would offer a favourable field for exploration. Mr. Hunter has been made acquainted with some particulars of an expedition composed of a party of Americans to that part some years ago. They discovered abundant evidence of the country being rich in precious metals, but the hostility of the Indians, culminating in the massacre of nearly the entire party, prematurely terminated their investigations, the few survivors making their escape with much difficulty. Mr. Hunter says that this portion of the South American continent is inhabited by various Indian tribes who are believed to practise cannibalism, and that one tribe, the Pianoghottos, on the confines of British Guiana, are well known for their inveterate hostility to strangers, many instances having been recorded of their having repulsed and murdered boats' crews penetrating to their country from the Brazilian side.

SEVERAL parcels of land and fresh-water mollusks collected by Prof. José N. Rovirosa, mainly in the State of Tabasco, Mexico, were sent last summer to the Academy of Natural Sciences, Philadelphia. As some of them are of considerable interest, a list has been prepared by Mr. H. A. Pilsbry, and is printed in the latest instalment (Part III.) of the Academy's "Proceedings" for 1892. The list is illustrated with several figures brought together on a single plate.

THE bulk of fine gloves produced in Russia are made, it seems, from foal skins. So says the U.S. Consul-general at St. Petersburg in a recent report on the subject. Very little is done in Russia, he says, in the manufacture of gloves from sheep, goat, or kid skins. Much hand-labour is needed to prepare foal skins for gloves, and it is doubtful whether they could be profitably used in countries where hand labour is dear. When well dressed they are very durable, and at the same time delicate, and have a great advantage in taking well all sorts of dyes.

THE report of the United States Commissioner of Fish and Fisheries for the fiscal year ending June 30, 1889, has just been issued. Among the appendices is an elaborate and valuable report on the fisheries of the Pacific coast of the United States, by J. W. Collins. The scope of this report is limited to a consideration of such fisheries as are prosecuted in or from the region embraced between the southern extremity of California and the north-western limit of Washington. Incidentally, a somewhat extended reference has been made to certain phases of fishery in Alaska, in explanation of industries which are controlled by capitalists of San Francisco, or elsewhere, and constitute a part of the fishing interests of the region specially treated of in the report.

THE *Journal of Geology*, which is being issued from the University Press of Chicago, promises to be a periodical of much interest to geologists. Two numbers have been published, and among the contents are papers on the pre-Cambrian rocks of the British Islands, by Sir Archibald Geikie; geology as a part of a college curriculum, by H. S. Williams; an historical sketch of the Lake Superior region to Cambrian time, by C. R. van Hise; the Glacial succession in Ohio, by F. Leverett; traces of Glacial man in Ohio, by W. H. Holmes; and the volcanic rocks of the Andes, by J. P. Iddings.

MESSRS. GAUTHIER-VILLARS ET FILS have added to their "Encyclopédie Scientifique des Aide-Mémoire" a volume entitled, "Traité Pratique de Calorimétrie Chimique," by M. Berthelot, secretary of the Academy of Sciences. In the same series have been published "L'Art de Chiffrer et Déchiffrer les Dépêches Secrètes," by the Marquis de Viaris; "Unités et Étalons," by C. E. Guillaume; and "Principes de la Machine à Vapeur," by E. Widmann.

A VOLUME containing an excellent account of "The Story of the Atlantic Telegraph," by Henry M. Field, has been issued by Messrs. Gay and Bird. The "story" is one of profound interest, and the author tells it vigorously and clearly. He is a brother of the late Cyrus W. Field, and has therefore had access to many new and important sources of information. He does full justice to the part played by his brother in the great enterprise, but does not underrate the services rendered by "the science and seamanship, the capital and the undaunted courage, of England."

A SECOND edition of Mr. W. W. Rouse Ball's "Short Account of the History of Mathematics" (reviewed in NATURE, vol. xxxix. p. 265) has been issued by Messrs. Macmillan and Co. The author has revised the book and made some changes in detail, but he explains in the preface that the general character of the work—as a popular account of the leading facts in the history of mathematics—remains unaltered.

MESSRS. CASSELL AND CO. have published a fifth edition of "The Field Naturalist's Handbook," by the late Rev. J. G. Wood and the Rev. Theodore Wood.

MESSRS. ASHER AND CO., Berlin, have begun the publication of a series of reprints of remarkable writings and maps relating to meteorology and earth-magnetism. The series is handsomely printed, and edited by Prof. G. Hellmann. The first two numbers are L. Reynmann's "Wetterbüchlein von wahrer Erkenntniss des Wetters" (1510), and Pascal's "Récit de la Grande Expérience de l'Équilibre des Liqueurs" (1648).

MESSRS. C. GRIFFIN AND CO. have published the tenth annual issue of the "Year-Book of the Scientific and Learned Societies of Great Britain and Ireland." The work comprises lists of the papers read during 1892 before societies engaged in fourteen departments of research, with the names of the authors.

MESSRS. FRIEDLÄNDER & SON, Berlin, have published an inaugural dissertation, prepared with a view to the attainment of a doctor s degree at Göttingen, by Johannes Müller, embodying the results of researches on the anatomy of Compositæ. The essay is illustrated with four plates.

A CATALOGUE of the types and figured specimens in the geological department of the Manchester Museum, Owens College, by Herbert Bolton, has been issued as one of the "Museum Handbooks." In the same series appear an "Outline Classification of the Vegetable Kingdom," by F. E. Weiss, and a second edition of Prof. Milnes Marshall's "Outline Classification of the Animal Kingdom."

THE Geological and Natural History Survey of Minnesota has published as one of its Bulletins (No. 7) a volume on "The Mammals of Minnesota." It is described on the title-page as "a scientific and popular account of their features and habits." The work is illustrated with twenty-three figures and eight plates.

A WORK on the "Geology of the Eureka District, Nevada," with an atlas, by Arnold Hague, has been published by the United States Geological Survey. It forms the twentieth volume of the Survey's "monographs." The author explains in the preface that the work is purely geological in its scope and is mainly a careful study and survey of a comparatively small block of mountains, which may be designated the Eureka Mountains, but which should not be confounded with the Eureka mining district, as several other well-known but less important mining districts lie wholly within the same mountain area.

THE first part of M. E. Burnat's important *Flore des Alpes Maritimes* has just been published.

A REPORT of the results so far obtained from Bornmüller's botanical travels in southern Persia is published in the *Mittheilungen* of the Thuringian Botanical Association.

DR. P. H. MELL has prepared for the U.S. Department of Agriculture a valuable report on the climatology of the cotton plant.

AN important series of well-crystallising double halogen salts of tellurium with potassium, rubidium, and cæsium, have been prepared by Mr. H. L. Wheeler, and are described in the current number of the "Zeitschrift für Anorganische Chemie." They correspond to the general formula M_2TeR_6, where M represents potassium, rubidium, or cæsium and R chlorine, bromine, or iodine. They all crystallise in octahedrons belonging to the cubic system, in this respect resembling the platinochlorides and other kindred double halogen salts of that type. The crystals of the chlorides possess a bright-yellow colour, those of the bromides various shades of deep red, while those of the iodides are quite black and opaque. In order to prepare the chlorides, tellurium is converted into tellurious acid by means of nitro-hydrochloric acid; the solution is evaporated to dryness, and the residue dissolved in hot hydrochloric acid. Upon adding to the solution of tellurium tetrachloride so obtained an aqueous solution of the chloride of the alkali metal, a crystalline precipitate of the double chloride is obtained. In the case of the cæsium salt, Cs_2TeCl_6, a precipitate is obtained even in very dilute solutions, owing to the difficult solubility of the salt. Upon boiling the precipitate dissolves, and on cooling brilliant little yellow octahedrons are deposited. The presence of excess of either cæsium chloride or tellurium tetrachloride is quite immaterial; indeed, the salt may be recrystallised from a solution of either. Water at once decomposes it, with production of a voluminous white precipitate of tellurious acid H_2TeO_3. It is only stable in solution in presence of a little free hydrochloric acid. Concentrated hydrochloric acid precipitates it from solution in the form of microscopic octahedra. The rubidium salt, Rb_2TeCl_6, is more soluble so that precipitation only occurs in concentrated solutions. The crystals, moreover, are usually much larger than those of the cæsium salt. The potassium salt, K_2TeCl_6, is much more soluble, and is even deliquescent. An excess of tellurium tetrachloride is necessary in its preparation, and it is best obtained in good crystals by spontaneous evaporation of a dilute hydrochloric acid solution.

THE bromides are obtained by dissolving finely divided elementary tellurium and caesium bromide in dilute hydrobromic acid containing excess of bromine. In the preparation of the cæsium salt, Cs_2TeBr_6, the solution is effected at a moderately elevated temperature, and the concentrated solution deposits large brilliant red octahedrons of the salt upon cooling. The rubidium salt, Rb_2TeBr_6, is readily obtained in magnificent deep red octahedrons by spontaneous evaporation of the solution prepared at the ordinary temperature. In preparing the potassium salt, if a hot solution is made, octahedral crystals of the anhydrous salt, K_2TeBr_6 are obtained, but if the concentration is effected by spontaneous evaporation light red coloured rhombic crystals of a hydrated salt, $K_2TeBr_6 \cdot 2H_2O$, are deposited. The iodides are prepared by addition of the alkaline iodide to a solution of tellurious acid in hydriodic acid. The cæsium salt, Cs_2TeI_6, is so difficultly soluble that it was only obtained as a finely divided black powder. The rubidium salt, however, Rb_2TeI_6, is more soluble and is precipitated in microscopic black octahedrons. The potassium salt is deposited in the hydrated form, $K_2TeI_6 \cdot 2H_2O$, in long monoclinic prisms which lose their water of crystallisation at 100 – 115° and become converted into a dull black powder consisting of the anhydrous salt.

SIMULTANEOUSLY with the above work of Mr. Wheeler, Drs. Muthmann and Schäfer, of Münich, have been engaged in investigating the formation of double halogen salts of the alkali metals with tellurium and selenium, and in the current number of the "Berichte," an account of some corresponding selenium compounds is given. Analogous chlorides were found to be incapable of preparation in presence of water, but the corresponding potassium and ammonium selenium bromides have been obtained in good crystals. When selenious acid is dissolved in hydrobromic acid and to the solution of selenium tetrabromide thus formed a solution of potassium bromide is added, and the mixture evaporated and allowed to cool, a deep orange-coloured precipitate is produced, consisting of small regular octahedrons of potassium selenium bromide, K_2SeBr_6. These crystals are decomposed by water like those of the tellurium salts previously described, a colourless solution being obtained which contains selenious and hydrobromic acids and potassium bromide. They dissolve without decomposition, however, in dilute hydrobromic acid and separate from the solution again upon evaporation. The ammonium salt $(NH_4)_2SeBr_6$, is likewise readily obtained by employing ammonium bromide instead of potassium bromide. A precipitate of minute dark-coloured regular octahedrons is usually at once obtained upon adding the ammonium bromide, and the mother liquor after filtration yields by spontaneous evaporation beautiful garnet red octahedrons, modified by faces of the cube, which frequently exceed half a centimetre in diameter and exhibit a brilliant semi-metallic lustre.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include a number of the Lucernarian *Depastrum cyathiforme* (one individual exhibiting a lateral bud), several varieties of the Actinian *Thoë* (*Sagartia*) *sphyrodeta*, the Mollusca *Sepiola atlantica*, *Philine aperta* and *Æolidiella Alderi*, and species of the Cumacean genera *Diastylis*, *Iphinoë* and *Pseudocuma*. There has been no noteworthy change in the floating fauna. The following animals, in addition to the larger number of those already recorded, are now breeding:—the Actinian *Urticina felina* (= *Tealia crassicornis*), the Cumacean *Pseudocuma cercaria*, the Brachyura *Xantho floridus* and *rivulosus* and the Echinid *Echinus miliaris*.

THE additions to the Zoological Society's Gardens during the past week include a Chacma Baboon (*Cynocephalus porcarius*, ♂), a Lion (*Felis leo*, ♀) from South Africa, presented by Mr. Frederick Vaughan Kirby; a Mozambique Monkey (*Cercopithecus pygerythrus*, ♂) from East Africa, presented by Mr. Lewis Atkinson; a Sykes's Monkey (*Cercopithecus albigularis*, ♂) a Garnett's Galago (*Galago garnetti*) from East Africa, presented by Mr. Thomas E. C. Remington; a Diana Monkey (*Cercopithecus diana*, ♀) from West Africa, presented by Surg.-Major S. J. Flood; a Japanese Deer (*Cervus sika*, ♂) from Japan, presented by Mr. C. J. Lucas; two Emus (*Dromæus novæ-hollandiæ*) from Australia, presented by Mr. Charles E. Milburn; four Sociable Marsh Hawks (*Rostrhamus sociabilis*) from South America, presented by Mr. G. R. Gibson; two Madagascar Weaver Birds (*Fondia madagascariensis*) from Madagascar) presented by Mr. Ginn; a Laughing Kingfisher (*Dacelo gigantea*) from Australia, presented by Mr. W. B. Brett; a Radiated Tortoise (*Testudo radiata*) from Madagascar, presented by Mr. B. Smith; a Bonnet Monkey (*Macacus sinicus*, ♂) from India, (two Mexican Guans (*Penelope purpurascens*) from Central America, a Wattled Guan (*Uburria carunculata*) from United States of Columbia, deposited; a White-lipped Peccary (*Dicotyles labiatus*, ♂) from South America, an Orange-winged Amazon (*Chrysotis amazonica*) from South America, twelve Spotted Salamanders (*Salamandra maculosa*) European, purchased; a Reindeer (*Rangifer tarandus*, ♂) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE TOTAL SOLAR ECLIPSE (APRIL, 1893).—In *Comptes Rendus* for March 15 (No. 20) M. Deslandres gives a brief preliminary account of some of the main results that he has been able to gather from the photographs taken by him during the recent total solar eclipse. The instrumental equipment that he had, enabled him to obtain photographs of the corona, to study its spectrum, to examine the coronal light in the most refrangible part of the ultra-violet region, and to measure the rotation of the corona by the method of the displacement of lines in the spectrum. The coronal photographs showed luminous jets of a length equal to twice the diameter of the sun, while the general outline had a form somewhat usual at times of maxima spot frequency. With regard to the spectroscopic results, the large dispersion that was employed in one case was found to have been too great; but from the photographs taken with the small dispersive instrument at least fifteen new coronal and chromospherical lines have been discovered. Perhaps the most interesting results obtained relate to the rotation of the corona. The negatives showed the spectra of two points exactly on opposite sides of the corona, situated in the equatorial plane of the sun, at a distance equal to two-thirds of his diameter. The lines in the spectra indicated large displacements, which on measurement were found to correspond to velocities of 5 and 7 kilometres. The conclusion to be gathered from such a result as this is that the corona must travel nearly with the disc in its motion and thus be subject to its periodical rotational movement.

THE ECLIPSE OF APRIL, 1893.—It is very satisfactory to hear that the photographs taken by the English party situated at Fundium, on the west coast of Africa, have, on closer examination, turned out very excellent. There seems great reason also to believe that many old points may be cleared up, while hope is also entertained of raising some new ones.

FINLAY'S PERIODIC COMET.—A telegram from Kiel informs us that Finlay's comet has been found. It runs as follows:—

18 May, 16h. 15m. 6s., Capetown
R.A. 355° 30′ 18″ N.P.D. 95° 1′ 50″
Dim.

VARIABLE STAR NOMENCLATURE.—Now that a systematic means has been adopted for numbering the minor planets until their orbits are fully recognised, much unnecessary confusion has been avoided. Just as it was with asteroids so it is with variable stars, many stars being termed such although their variability has not been confirmed. To correct such errors and to eliminate various other sources of mis-notation, such as that of putting a catalogue letter in front of the constellation in which the star is situated, when another star in the constellation is so known in the star maps, Prof. Chandler adds a few notes with reference to the catalogue which will now soon be forthcoming (*Astronomische Nachrichten* 3161). He also gives a partial list of some of the letters that will be adopted to avoid further complexity.

JUPITER'S SATELLITES.—In this column, vol. xlvii., p. 518, we referred to the important work that was being carried on at Arequipa by Prof. Pickering with reference both to the telescopic appearances of Jupiter and his system of satellites. Since that time further observations, more especially of the satellites, have occupied his attention, and an account of them is given in the current number of *Astronomy and Astrophysics* (No. 115). The first investigation he undertook was to find out whether the rotations of the satellites on their axes were retrograde or direct. To do this the alternate lengthening and shortening of the discs were minutely observed, use being made of the revolution of the earth, since it is on this account that after opposition with *direct* motion of rotation a given phase will be presented earlier, and with retrograde motion a given phase will be presented later than if the observations had been made from the centre of the sun. Working with the first satellite it was found that a series of observations occupied about two hours, and upon the hypothesis of a *direct* rotation the synodic period was 13h. 3m. 25·8s., and upon a *retrograde* motion hypothesis, 13h. 3m. 10·8s. The conclusion of the discussion of the observations here given is that the rotation is probably retrograde. In the clear air of Arequipa, and with excellent instrumental equipment, Prof. Pickering has been able to make many quite unique observations. We have mentioned before the flattening of the disc of the second satellite when about to undergo an occultation. This observation has later been confirmed, and thus shown to be a genuine observed fact. The reappearance of the third satellite on January 27 has given perhaps a better series of observations of this atmospheric effect. When the satellite was half uncovered "it was noted that the cusps were distinctly rounded as in the case with the sun when near the horizon, as seen from a high mountain peak." That Jupiter is not self-luminous, and that outside its cloud surface is situated a rare atmosphere capable of producing a measurable refraction, are two of the results of these observations, and taking the refraction at the cloud surface, the value $0''\cdot50 \times 0''\cdot05$ probably is not far from the truth.

THE MOON'S SURFACE.—Under the title of "The Moon's Face," a study of the origin of its features, we have before us a small book of fifty pages, containing the address, as retiring President, of Mr. G. K. Gilbert, before the Philosophical Society of Washington (*Bulletin*, vol. xii., pp. 241–292). After giving a short survey of the various theories that have from time to time been suggested as explaining the origin of the features on our satellite's surface, Mr. Gilbert has been led to put forward what he terms a "moonlet theory," which "not only harmonises with the varied details of crater character, but aids in the explanation, and even in the history, of the other features of the moon's surface." The hypothesis may be stated as follows:—Previous to the existence of the moon the earth was circled by a ring analogous to that which surrounds Saturn. The small bodies or satellites constituting this ring in time gradually coalesced, first into a large number of nuclei, and finally into one, this nucleus being our moon. The lunar craters are, to use Mr. Gilbert's own words, "the scars produced by the collision of those minor aggregations, or moonlets, which last surrendered their individuality." In discussing this hypothesis the inquiry is carried on three lines: an investigation of the ellipticity of the lunar craters, experimental investigation of the relation between the angle of incidence and ellipticity of impact craters, and of the orbital relations affecting the incidence angles of moonlets. With regard to some of the peculiar features of the lunar surface, let us briefly refer to some of the explanations given here. In the production of small craters small moonlets were employed, the cups being moulded as the result of collision. For large craters, greater moonlets are supposed to have been in action, the rims round the cups being raised partly by the overflow at the edges of the cup, or resulting in the upheaval of the surrounding plain in all directions. The central cone is accounted for by supposing that the top parts of the walls of the cup are so "weakened by the efforts of heating," that they consequently fall into the centre of the cup from all sides. In the region of the Mare Imbrium he supposes that a collision of great violence occurred, dispersing in all directions a deluge of material "solid, pasty, and liquid." The outrush from the Mare Imbrium thus introduces the elements necessary to a broad classification of the lunar surface. Smooth planes were produced by the liquid matter, parts were ground or sculptured by the solid matter, while some features were left entirely untouched. Such are one or two of the origin of surface features as put forward by Mr. Gilbert in his moonlet theory. That they are ingenious and lack not interest is true, but that the hypothesis itself is likely to be received with anything like favour seems very doubtful, since our present knowledge of the way nature works shows us that the last minor aggregations or moonlets could not very probably act in the way indicated above, because the state of the nucleus about that time would be one of intense heat in consequence of the collisions, and therefore would not be capable of receiving lasting impressions as required by the hypothesis.

AMÉDÉE GUILLEMIN.—It is with great regret that we have to record the death of M. Amédée Guillemin, which occurred recently in France. Many of our readers will have read the most interesting and valuable books which he wrote, setting forth scientific facts in a popular light. Of his many writings perhaps that which is most familiar to us are the volumes entitled "The Heavens" and "The Forces of Nature," as translated into English, and it is only quite lately that we had occasion to notice a small volume, evidently his last work, dealing with astronomical subjects, and entitled "L'Autres Mondes."

GEOGRAPHICAL NOTES.

LIEUTENANT R. PEARY, the explorer of North Greenland, has been reluctantly compelled to relinquish his projected lecturing tour in Europe, as all his time must be devoted to preparations for his new expedition toward the North Pole, which he hopes to commence this summer.

THE Governments of Sweden and Denmark have entrusted Prof. Otto Pettersson with the planning and direction of a series of simultaneous observations on the physical condition of the Skagerrack, Kattegat, and Baltic Sea. These observations are to be made on four days, three months apart, and commenced on May 1, 1893. Simultaneous observations between the Moray Firth and the north of Shetland would greatly enhance the value of the Scandinavian results, and it is possible that the Fishery Board for Scotland may undertake this work, at least on some of the observing days.

CAPTAIN RICHARD PIKE, well known as an Arctic navigator in recent American expeditions, died at St. John's, Newfoundland, in the beginning of May. In 1881 he conveyed the Greeley expedition to Lady Franklin Bay, and would have brought relief to the party, and saved the gallant explorers from their terrible experiences of starvation in 1883, had he not on that occasion been put under the orders of a United States cavalry officer, whose mismanagement ruined the expedition. Captain Pike's last Arctic work was the transport of Peary's expedition to McCormack's Bay, and his return for them in the sealer *Kite*. He had the reputation of being the best practical navigator of the Newfoundland Sealing Fleet, and his experience will be missed in connection with Lieutenant Peary's new expedition, which Captain Pike was to have taken north this summer.

THE anniversary meeting of the Royal Geographical Society will be held on Monday, the 29th, at 2.30 p.m. From the circular calling the meeting we observe that a very considerable change in the composition of the Council is contemplated. The President, Sir M. E. Grant Duff, does not seek re-election, in the hope, as he hinted at the anniversary dinner, that his "leap into the gulf in the cause of women" will heal the recent dissensions in the Society, and enable the scientific work in which it is engaged to be carried on without interruption. Mr. Clements Markham, F.R.S., has accepted the nomination of the Council as President. Captain Wharton, R.N., F.R.S., is proposed as a new Vice-President, and the following, amongst other names, are proposed as new members of Council:—Admiral Lindesay Brine, General T. E. Gordon, author of "The Roof of the World;" Mr. G. S. Mackenzie, of the British East Africa Company: Colonel C. M. Watson, and Mr. W. H. Hudlestone, F.R.S., President of the Geological Society. These nominations are subject to the approval of the annual meeting, which is expected to be unusually large and representative.

BACTERIA, THEIR NATURE AND FUNCTION.[1]

A WELL-KNOWN English writer a short time ago informed the public that Prof. von Pettenkofer, the distinguished veteran in sanitary science in Munich, expressed the opinion that "the atmospheric envelope of this globe is at present in a bacillophil humour." Expressions such as these have been repeatedly used in one form or another, some more, some less witty; the intention being, of course, to convey an exaggerated impression of the frame of mind of over-zealous enthusiasts. By such expressions more or less distinguished speakers and writers have been enabled to exhibit the smartness of their phraseology. Thus one distinguished professor relieved the anxiety of his students by the jocular observation that idleness and laziness will probably be found to be due to a specific bacillus, while another no less profound writer enunciated that crime and inebriety are probably due to bacilli. With regard to the distribution of bacteria, as well as with regard to their action, we meet with statements which are almost made humorous by smartness of exaggeration. Under the cover of the title "Science Notes," one of the London papers offered to its readers for breakfast the following palatable dish:—"In a grain of butter you have 47,250,000 microbes; when you eat a slice of bread and butter, you therefore must swallow as many microbes as there are people in Europe." Here it ought to be stated that a grain of solid matter of *London sewage* contains only a small fraction of this number of microbes. But leaving these silly exaggerations and those grotesque sayings to their authors for

[1] Lecture delivered at the London Institution, on February 27, 1893, by E. Klein, M.D., F.R.S., Lecturer on General Anatomy and Physiology at the Medical School of St. Bartholomew's Hospital, London

further improvement, it is nevertheless well established that a considerable number of phenomena in nature are intimately associated with bacterial life. The world of bacteria is comparable to an unseen flora which, in variety of character, of activity and importance in the economy of nature, compares with the visible flora, and in its extension and area of distribution is as great as, in some respects greater than, that of the visible vegetable and animal kingdom. Though unpreceived by the unaided eye, this bacterial world forces itself, by its multifarious activity, continually on our attention; it comes into prominence by the vast effects, the slow but far-reaching results which it produces on man, animal, and plant, for good and for evil, in life and in death. Some of these actions I shall have the honour to bring before you this evening, and you will see that while there are bacteria whose actions are undesired and not conducive to the well-being of man or animals, there are others which are of the greatest service both to them and to plants, and are an essential and integral part in the economy of nature.

I spoke just now of the bacterial world as of an unseen flora; I meant by this a part of the vegetable kingdom not perceived by the unaided eye, though, as you will see, it is easily brought to perception by a variety of means. The individuals that constitute the bacterial world are, as is no doubt known to you, of such extremely minute size that only by the aid of the microscope can they be seen, their size being often less than $\frac{1}{25000}$ or $\frac{1}{50000}$ part of an inch, rarely more than $\frac{1}{3000}$ part of an inch. They are spoken of as having the character of plants, because the elements, like those of a plant, are invested in a sheath of cellulose, within which is contained the essential part, the living protoplasm, the bacterial individuals being in fact comparable to unicellular plants, in which, however, no definite cell nucleus has been hitherto demonstrated. It ought, however, to be mentioned that various observers have attempted to show, and, by complex methods of staining, have succeeded in showing in some bacterial species the existence of parts which resemble, and which are considered as comparable to, the nucleus forming an integral part of the typical vegetable cell.

In speaking of bacteria as of plants there are other than morphological characters which guide us in this designation; bacteria resemble plants in this essential, that they possess the power to build up, out of simple organic compounds, the most complex substances such as the protoplasm of their own bodies. There are known not a few bacterial species which grow and multiply, *i.e.* which build up their highly complex nitrogenous albuminous substances at the expense of relatively simple nitrogenous bodies, such as ammonium tartrate, urea and allied substances, or which can do this even by the absorption of free nitrogen of the air. Other species require for their growth and multiplication as complex nitrogenous substances as the animal body itself, and like this latter are capable of breaking them up into simpler combinations. Pathogenic bacteria—many of the species concerned in the decomposition and putrefaction of albuminous substances—belong to this group.

All bacteria multiply by division; hence their name, schizomycetes, or fission fungi, the typical process of multiplication consisting in the enlargement of an individual, and in subsequent splitting into two by fission, at the conclusion of which process two new individuals are the result, each of them capable of enlarging and again dividing in the same way into two, and so on. But it can be easily shown by comparative observations and examination of suitably prepared specimens of artificial cultures of the different species that not seldom the process of multiplication does not follow this line.

I show you here a lantern slide of a microscopic specimen of one of those species which, owing to the spherical or nearly spherical form of the elements, is called a coccus, or micrococcus; and owing to the manner of growth in clusters and continuous masses, is called a staphylococcus; this microscopic specimen has been obtained by the method of making "impression preparations," that is to say, by means of a thin glass pressed on to a recent, *i.e.* a young colony or colonies growing on the surface of a solid medium, an exact impression is obtained of the growth, and a good and correct insight is obtained of the manner in which the colony enlarges, and the way in which the individuals constituting the colony grow and multiply. You see in this photographic representation that there are a good many individuals many times (4–10 times) as large as others, that some of these large elements are uniform, while others show just the indication of a transverse fissure by which the large element is dividing; still others show two fissures at right angles, by which the big element becomes divided into four smaller ones. But you see also the majority of cocci are only minute dots, some in pairs, others in clusters, the former looking like two demilunes separated by a straight clear line; in fact, this latter appearance denotes the typical manner in which one coccus, having first enlarged a little, divides into two small elements. But the presence of the huge elements mentioned above tells us also that one coccus may go on growing to a very large size without dividing, and having reached this huge diameter, then commences to divide, first into two, then into four, eight, and sixteen individuals of the typical size.

I show you here an impression preparation of a recent colony of another species (*Bacillus coli*), the individuals of which are rod-shaped or cylindrical, and are what are called typical bacilli. Here the great majority of the individuals are of cylindrical shape, and of a fairly uniform size; a few only are shorter, and arranged in the form of a dumb-bell, indicating that one of the longer individuals has by fission split up into two smaller individuals. But if you look at a third impression preparation, of which I here show you a photograph (Proteus), you will see that while there are a few chains of cylindrical bacilli, indicating successive division of the individuals and the new offsprings remaining joined end to end—thus constituting what is spoken of as a leptothrix—there are other threads in the colony which either show a division into cylindrical elements only imperfectly or not at all, appearing uniform and unsegmented threads; where the segmentation is imperfect the individuals are of very various lengths, some not longer than those typical bacilli in the first-mentioned chains, others three and more times as long. These appearances indicate that the multiplication of the bacilli does not always take place in that typical manner in which it is generally represented, viz. one individual elongates a little, then splits up into two short individuals; but a bacillus may go on elongating till it reaches the manifold length of the typical rods, and having reached this great length then segments into a great number of cylindrical rods. This mode of multiplication can be made out not only in these impression preparations, but can be actually observed in the fresh condition under suitable conditions, *e.g.* on the warm stage.

That this mode of growth appertains not only to cocci and bacilli, but also to the third morphological group of bacteria, viz. the vibrios, or spirilla, is ascertained by the fact that often one vibrio, *i.e.* a more or less curved rod-shaped individual or a comma-shaped bacillus, grows into a uniform homogeneous spiral or wavy thread, which is capable of splitting up into a number, *i.e.* a chain of comma-shaped vibrios.

We have then the typical mode of division, by which one individual, a coccus, or bacillus, or vibrio, as the case may be, slightly enlarges, and then by fission divides into two; or an individual continues to grow to abnormal size or length, and then splits up into a series of individuals of the typical size; this latter mode of multiplication implies a deficiency of fission for the time being, and is not, as far as can be made out, due to any abnormal conditions affecting the growth, for in many species this occurs in recent and active colonies under conditions which in all other respects must be pronounced as favourable for growth and multiplication.

Another interesting appearance, shown by some species of bacteria, is generally ascribed to degeneration or involution, *i.e.* the bacteria assume peculiar abnormal shapes stated to be due to abnormal influences, insufficient or unfavourable soil, unfavourable temperature, &c., &c.; but while it is true that such influences do produce abnormal shapes, disintegration, &c., there are certain changes in shape that are observed in some species of bacteria while growing under perfectly favourable conditions and with the normal rapidity, and which are anything but degenerating.

A recent colony of the bacillus anthracis, like the photograph I show you here, growing on nutritive gelatine, is made up of twisted and convoluted threads of cylindrical rods, which threads are seen to shoot out and to extend like filaments from the margin of the colony. Now, you notice in the next photograph that instead of these filaments being made up of the typical cylindrical rods the former consist of relatively huge spindle-shaped or spherical masses many times the diameter of the typical rods. The threads of this colony are perfectly active, and are growing with vigour and in perfectly normal circumstances as regards soil, temperature, and all other known conditions. As a matter of fact, a few days later, as comparative specimens show, all threads may be, and as a rule are, again of the typical aspect, *i.e.* uniform threads and chains of rod-shaped elements.

Another photograph which I show you here is from a colony of the bacillus of diphtheria. Here also you notice the appearances already mentioned of the anthrax bacilli, viz. shorter or longer filaments, in which some of the elements show a conspicuous enlargement: pear-shaped, spherical, or club-shaped. Such forms are not involution forms: they occur in vigorous and actively growing young colonies.

A still further illustration, and one of great importance, is shown by this photograph, illustrating a similar change of the tubercle bacilli. This change has now been confirmed by several independent observers. The typical tubercle bacilli of human or bovine tubercle and of early cultivations are cylindrical rods. In cultivations of long duration but still actively growing you notice forms which are more filamentous, and, as in the present illustrations, are branched filaments with club-shaped enlargements.

From all this the conclusion is justified that in all these cases of bacilli the typical cylindrical bacilli show occasionally an indication that reminds one of forms belonging to the higher or mycelial fungi, in which the growing filaments remain unsegmented and become thickened and even branched. These thickened, branched, and club-shaped forms of the bacilli would correspond to an atavism, and would recall a probable former fungoid phase in the evolutional history of these bacilli.

The next point to which I wish to call your attention is the rapidity with which multiplication of the bacteria takes place. This differs according to the amount and nature of the nutriment or soil on which they grow, and to the temperature. While some bacteria multiply even at lower temperatures at a great rate, others do so only at higher temperatures. But in order to give you an idea of the power and the rate of multiplication I may mention the following:—Direct observations show that the rate at which bacteria divide at a temperature of 20°C. varies from eighteen minutes to thirty minutes or a little longer, and at higher temperatures correspondingly faster. A tube of nutrient broth was inoculated with a trace of the growth of a staphylococcus (*Staphylococcus pyogenes aureus*), the number of cocci introduced into the tube having been previously determined to be 8 per cubic centimetre. The tube was then kept at 37°C.; in the first twenty-four hours the cocci had multiplied to 640,000 per cubic centimetre; in the second twenty-four hours to 248 millions per cubic centimetre, and in the third twenty-four hours to 1184 millions per cubic centimetre.

A point of interest is the motility exhibited by some bacteria. In some species most, in others comparatively few, individuals show active locomotion, spinning round and darting to and fro; in many other species no motility is observed. In the motile species it is known that this motility is due to the presence and active motion of cilia or flagella, and these have been seen and photographed in former years in some of the larger forms, but only within recent years has it been possible, by means of new methods (Löffler), to actually demonstrate in the smallest forms these flagella, and here the remarkable facts have been shown that while some possess only one flagellum at one end, in other species the bacillus possesses a bundle of them, or is covered with the flagella on its whole surface. I show here some photos of the flagella, one possessing two flagella at one end (spirillum volutans), the other (cholera bacillus) one at one end, and the third (typhoid bacillus) is covered with quite a number of flagella.

A not less interesting point is the formation of spores: the only trustworthily ascertained mode of spore formation is that which is called endospores, as is shown in the following photograms; a bacillus at a certain phase develops in its protoplasm a minute glistening granule, this increases in size and becomes oval, while the rest of the substance of the bacillus becomes pale, swells up and gradually degenerates and disappears, leaving the fully formed oval bright spore free. These spores are of great resistance to temperature, chemical obnoxious substances, drying, &c., so that even after long periods and various adventures, when again brought under proper and suitable conditions, they are capable of germinating into the bacilli. These then grow and divide and continue to do so, producing new crops. Non-sporing bacteria are for this reason more liable to succumb in the struggle for existence, although many species of non-sporing bacilli have such a vast power of multiplication and are so little selective in their requirements that they manage to keep their crops perpetually going; some notorious putrefactive cocci and bacilli belong to this class. Having now mentioned the essential features in the morphology of bacteria, as far as is possible in the limited space of time at my disposal, I proceed to give you a short summary of some of the most important activities which bacteria exhibit.

Bacteria causing Decomposition of Albumen.

Foremost in importance and vastness of result is the action which certain species of bacteria have on albuminous matter, an action which is termed *putrefactive decomposition of albumen*, animal or vegetable. All organic matter when deprived of life is resolved into simpler compounds, is broken up into lower nitrogenous principles, like leucin, tyrosin, indol, phenol, &c., of which the ultimate products are ammonia, nitrites, and nitrates. The plant, it may be said in a general way, builds up albuminous matter from nitrates, this albuminous matter it is which forms the protoplasm of its cells, this albuminous matter it is which serves as nitrogenous food for animals; these again supplying the food for other animals and man. In the living body of these the albuminous matter becomes broken up, yielding nitrogenous principles like urea and allied substances, which again, after further oxidation in the soil and in water, serve to supply nitrates to the plant; but also the bodies of animals and plants after death form a large stock from which by a long chain of processes, induced and sustained by micro-organisms, lower nitrogenous compounds, and ultimately ammonia and nitrates are produced, from which the living plants principally draw their nitrogen.

From this it is evident that the vegetable kingdom is dependent for its nitrogen chiefly on processes by which from the albumen of dead organic matter, by the activity of micro-organisms, in the first place lower nitrogenous principles and ultimately ammonia, and in the second place, also by micro-organisms nitrites and nitrates are formed. Now, the micro-organisms which are capable of producing the first series of decompositions of dead albuminous matter form, so to speak, the first army of attack; it is this army which, while multiplying at the expense of albumen, decomposes it, and thereby is instrumental in changing it into lower nitrogenous principles such as leucin, tyrosin, indol, and ammonia. Amongst the large number of species of putrefactive bacteria I will describe two only, which by their great distribution may be considered as playing a very important part in this decomposition of albumen. The first is the species known as *Proteus vulgaris*, the second is the *Bacillus coli*.

(*a*) *Proteus vulgaris*.—This species is the common putrefactive organism; it is almost invariably present in dead and decaying albuminous matter; it is the organism which in dead animals and man plays the principal part in the destruction and resolution of the body; it is present in the cavity of the normal intestine; it is found in connection with effete and dead matter occurring in the body in health and disease; it has a wide distribution in nature, and is present wherever organic matter happens to be in a state of putrescence; it is liable to pass from this and to be transmitted to other putrescible matter by air currents, by dust, by water, by human contact or otherwise, and then to set up in this new organic matter the same state of putrescence. The same applies to the bacillus coli, which has also a very wide distribution, and which is in most instances associated with putrefaction and decomposition of albuminous matter; it is a normal inhabitant of the human and animal intestine, and from here often passes into the soil, water, and air.

These two species of organisms may be considered then as being of great importance in the destruction and resolution of putrescible matter, in short of dead albuminous matter.

I show you here photographs of these two species as they appear in artificial cultures, under various forms of cultivation, and under the microscope under a magnification of 1000. Both these species are motile bacilli.

The *Proteus vulgaris*, as its name implies, presents itself in forms so varied, that it is at first sight difficult to recognise them as belonging to one and the same species: coccus forms, short ovals, short and long cylinders, homogeneous long threads, and even spiral forms. But by artificial cultivation by exact methods they can be shown to belong to one and the same species; and it can also be shown that under particular conditions of cultivation the bacillus almost invariably shows itself as cylindrical and thread-like forms; whereas under other conditions it assumes the character of cocci and ovals. The photographs which I show you here give an exact representation of these cylindrical and thread like forms observed in early gelatine plate cultures; later on, when the growth has proceeded for some days, and the gelatine has almost entirely become liquefied, the majority of the individuals are very short—either coccus-like or short ovals.

It is on account of this unstable or protean character of its form that Hauser gave it the name of Proteus, and being the common microbe of putrid decomposition, he called it *Proteus vulgaris*.

This organism, as a first and important action, peptonises albumen and liquefies and peptonises gelatine; then this peptone is decomposed, yielding, amongst other substances, leucin, tyrosin, indol, skatol, phenol, and further, ammonia.

(*b*) *The Bacillus coli.*—The normal inhabitant of the intestine of man and animals is another powerful albumen decomposing microbe, but, unlike the proteus, it decomposes albumen without first converting it into peptone; it therefore does not liquefy gelatine like the proteus; it rapidly decomposes albumen, forming indol and allied bodies, and even ammonia.

Bacteria causing Ammoniacal Fermentation of Urea.

In connection with these true putrefactive bacteria I have to mention a group of bacteria which, though not strictly connected with decomposition of albuminous matter, play an important part, inasmuch as their action supplements that of the former, the group in question consisting of species which can change urea and allied substances into ammonium carbonate. This action is generally and justly considered of the nature of a ferment or hydrating action, like that of other organised ferments to be presently described. But we mention this group here because by changing urea into ammonium carbonate it prepares, in one sense, the way for the action of certain other bacteria which, by oxidising ammonia into nitrites and nitrates, are the direct food-providers for the vegetable kingdom. Urea and allied substances, as stated above, are the last products of albuminous metabolism in man and animals, and therefore form an integral part of the material destined for the soil in which the plants of our gardens and fields live and thrive. I show you here one of the species of this group—for there are several—the *micrococcus ureæ;* this is a coccus growing as a white staphylococcus, and forming connected masses in the natural or artificial culture media; it does not liquefy gelatine, grows extremely rapidly at higher temperatures.

The photographs give you an idea of the character of this organism in plate, in streak- and stab-culture, and in microscopic specimens; in these latter you notice that neither in size, nor arrangement, nor mode of division does this microbe show anything that would distinguish it from other species of staphylococcus; its action on urea being its chief distinguishing character, being capable of converting it into ammonium carbonate.

At present it is well established that nitrogenous principles like indol, phenol, and ammonia are produced during the decomposition of albumen by proteus, bacillus coli, and other putrefactive bacteria; and, further, that substances, as indol, phenol, and the like, are, by the activity of certain other bacteria not yet sufficiently investigated, converted into ammonia. We have now traced the decomposition of albumen down to ammonia, and in this condition it is subjected in the soil to the action of the *nitrifying bacteria*—that is, bacteria which oxidise ammonia and convert it into nitrites and ultimately into nitrates; these bacteria complete then the series of processes by which the nitrogen ultimately returns from where it started. It started as nitrates in the soil surrounding the roots of plants, and as nitrates it ultimately again finds itself in the soil; first it had been used by the plant in order to build up its albumen, then as vegetable albumen it represents the food of animals; in these it serves to build up the protoplasm of the animal body, from which it passes as food for carnivorous animals. The albumen of animals or plants becomes decomposed by putrefactive bacteria, the ultimate products of this, ammonia, becoming converted by the nitrifying bacteria of the soil into nitrites and finally into nitrates. "From earth to earth" expresses the beginning and end of this wonderful migration and change!

Nitrifying Bacteria.

Schlœsing and Muntz were the first to show that the conversion of ammonia into nitrates in the soil is most probably caused by micro-organisms, but not till the researches of Warington, Winogradski, and P. Frankland, were these micro-organisms isolated and more carefully experimented with. Warington, and particularly Winogradski, have shown that there are two species of bacteria which play an important part in these processes, one species converting ammonia into nitrites, the other these finally into nitrates. I show you here some lantern slides of Winogradski, in which these two species are well shown; the slides are of preparations of artificial cultivations, in which Winogradski has been extremely successful. These two species (the nitrous and the nitric organism) are minute rod-shaped or oval bacteria; when in the act of dividing, they form short dumb-bells; the nitrous organism is larger than the nitric, but both show forms which possess celia, and which therefore are possessed of motility. Winogradski has by artificial cultivations obtained both these species in large quantities, and, on testing them on liquids of suitable composition, found that the one is capable of converting ammonia into nitrites, the other these latter into nitrates. There can then be no doubt that the problem of the manufacture on a large scale of these nitrifying microbes, so important for agriculture, must be considered as solved.

Bacteria of Leguminosæ.

I have now to introduce to your notice a group of organisms which, like the former, are of interest and importance to the vegetable kingdom, at any rate to one portion of it, viz. the plants belonging to the leguminosæ.

Hellriegel and Wilfarth had shown that the excess of nitrogen in leguminosæ is obtained from the atmosphere by the instrumentality of bacteria in the soil around the roots of the leguminous plants; that these bacteria "fix" the free nitrogen contained in the soil, derived, of course, from the atmosphere; and that if the soil be sterilised, by which the bacteria are killed, no fixation of nitrogen can take place, and the growth of the leguminous plant remains appreciably attenuated. The roots of leguminous plants growing in the ordinary soil are known to possess numbers of nodular growths. These nodules have been thoroughly investigated by a large number of observers, and their importance in the process of fixing the nitrogen, and in the proper development of the plant, has been satisfactorily worked out; foremost amongst these stand the investigations of Prof. Marshall Ward, of Sir John Lawes and Dr. Gilbert, of Beyerinck, Prazmowski, Nobbe, and Frank. Beyerinck, then Prazmowski, and particularly Nobbe, have shown that the nodules on the roots owe their origin to the growth in the tissues of the root of certain bacteria, and it is these bacteria which are instrumental in fixing the free nitrogen. These bacteria represent well-defined species, and, as Nobbe has shown, differ for the different leguminosæ.

My friend Prof. Marshall Ward has been kind enough to supply me for examination with roots of lupines containing the nodules, and I show you here some photos as the result of this examination, illustrating the distribution in the tissue of the nodules of particular species of bacteria, then the character of these bacteria under cultivations, and their aspect and size in microscopic specimens. This species of bacilli is composed of motile cylindrical rods, which, cultivated in gelatine, liquefy this, and produce in the liquefied gelatine a peculiar greenish fluorescent colouring; on agar they also produce this colouring; the nature of the young colonies in plate cultivation, their manner of spreading and swarming, are well shown in these photographs.

Chromogenic and Phosphorescent Bacteria.

Time does not permit of more than a passing allusion to those remarkable species of chromogenic bacteria which have the power to produce pigments, either pigments which become dissolved in the medium in which these bacteria grow, or remain limited to the substance of the bacteria themselves. Species of bacteria there are which produce pigments of scarlet red, orange, yellow, yellow-green, green, greenish-blue, blue, violet, or pink colour. The nature of these pigments and the meaning and object of their formation are still shrouded in a good deal of mystery, though Erdmann and Schrötter showed long ago that many points of similarity exist between some of these pigments and certain anilin colours. I show you here cultivations of some of those chromogenic bacteria, and in a diagram the spectrum of one species, viz. of the *Bacillus prodigiosus;* this is the more common of the chromogenic bacteria, being occasionally present in water and in air. The pigment is soluble in alcohol, though only to a limited degree, and when the spectrum of such a solution is examined it is seen to present a characteristic absorption-band in green; the spectrum of a watery distribution of these bacteria shows two bands: one narrow one in green, the other broader in greenish-blue; both are less deep than the single band of the alcoholic solution.

Nor have I sufficient time to do more than allude to another remarkable group of bacteria, which comprises several species, all having the power to produce luminosity of themselves and the medium in which they grow. These phosphorescent bacteria have been long known (Pflüger) to be concerned in the production of the phosphorescent condition of decomposing sea fish, but within recent times Ludwig, Fischer, Katz, and particularly Beyerinck have studied more in detail the conditions under which these bacteria grow, and have identified and cultivated several species. Dr. Beyerinck has kindly sent me one species of these phosphorescent bacteria. The elements of this species are short oval rods, often dumb-bells; they grow in fish broth, and when the growth becomes conspicuous to the unaided eye it is luminous when viewed in the dark. I show you here some cultures which, as you see, when I place them in the dark, show a beautiful phosphorescent appearance. The phosphorescence is more or less limited to the surface layer, that is the one in contact with the oxygen of the air; in the depth it is absent, but when shaking the flask the phosphorescence appears also in the depth.

Fermentation.

I have mentioned, in connection with a previous group, bacterial species which have the power to change by hydration urea into ammonium carbonate, a change which is called a fermentative action. Changes similar to these are caused by micro-organisms in many processes playing an important part in industries. Amongst these changes I may mention one in particular, the souring of milk. There are a good many others, the viscous or mannit fermentation, the butyric fermentation, the indigo fermentation, the dextran fermentation, the acetic acid fermentation, and others, but time does not permit me to describe more than one, viz. the common bacterium lactis. I show you here a number of photographs of the bacterium lactis under cultivation, and as seen under the microscope. It is a minute oval bacterium, which multiplies with great rapidity, and which, introduced into milk, turns this sour in 12 to 24 hours at the ordinary temperature; when sterile milk is inoculated with this bacterium and kept in a warm place at a temperature of 60° to 65° F., the milk is found solid and curdled before 20 or 24 hours are over, and in this curdled milk large numbers of the bacterium lactis are present either as dumb-bell ovals or as short chains. When a needle is dipped first into such curdled milk and then into normal milk, the same coagulation with the same appearances takes place in the latter. When a plate cultivation of such milk is made it is seen that a large number of colonies all of the same character are developed, which colonies are made up of the bacterium lactis; through however numerous generations this organism is cultivated in artificial cultivations,—it grows well on nutritive gelatine to which whey or only lactic sugar has been added—and if then transferred to fresh milk, it always produces this souring and curdling; that is to say, it changes lactic sugar into lactic acid, and as this is being formed it coagulates and precipitates the casein of the milk. With a trace of milk that has gone naturally sour—that is to say, to which the bacterium lactis has found entrance, and in which by its multiplication it has produced curdling, any amount of normal milk can be successively turned sour and curdled. The bacterium lactis is not by any means a rare organism; it is widely distributed, and can at any moment, in dairies and other places, through impurities of the utensils, by dust, &c., find access to milk which would soon succumb to its attacks; when, for instance, in dairies or in one or another locality the milk has a frequent tendency to turn sour, this means that the bacterium lactis has taken firm footing in such a locality. It is well known that only extreme measures of cleanliness, thorough boiling of all utensils and vessels, cleaning of walls and floors can banish or reduce it. In this the analogy with an epidemic of an infectious disease is obvious. Just as in an epidemic, every susceptible individual to which the contagion has had access becomes smitten by infection, and just as in an epidemic the contagium of the disease, being of wide distribution, and, having taken a firm hold of the locality, attacks an increasing number of individuals, and thus causes the epidemic—so also in the case of the bacterium lactis: when this has taken a firm hold of, and has acquired a great distribution in, any locality, any sample of milk (*i.e.* susceptible individual) may take the infection, either by coming in contact, directly or indirectly, with a trace of the milk already infected, *e.g.* by being placed in vessels in which infected milk has been kept previously, or becoming infected through dust charged with the bacterium lactis, or coming in contact with water poured from a vessel in which traces of the microbes were still left. All this finds its complete analogy in the case of an epidemic infectious disease. The fermentative processes due to microbic activity, and playing an important part in industries (alcoholic and other fermentations), illustrate in a very striking manner some of the essential features observed in the nature, in the production, and in the spread of infectious diseases in man and animals. The fermentative processes, thoroughly established as being due to microbic activity by the researches of Pasteur, were by Pasteur, and others after him, used as illustrations of the way in which infectious disorders in man and animals arise, and it was exactly these considerations which led Pasteur to his brilliant studies of these diseases, the results of which studies have been of such signal service in sanitary science in general, and in the prevention of infectious diseases in particular.

In the fermentative processes studied by Pasteur and others it was shown that each specific fermentative process is due to the growth and multiplication of a specific microbe. Just the same is the case with the infectious diseases—when from a substance which is in the process of fermentation, a trace containing the particular microbe is introduced into fresh fermentible substance, this latter undergoes the same fermentation; further, it is shown that, however great the number of accidental non-specific bacteria which may be introduced at the same time, unless that particular bacterium be present amongst them, the specific fermentative change does not ensue. The same is the case with infectious diseases: the number of non-specific bacteria in water, dust, air, various common articles of food, &c., is sometimes great, but no amount of these would set up any of the infectious diseases, like cholera or typhoid fever, tetanus or diphtheria; in order to do so there must be amongst them the particular microbe of cholera or typhoid fever, &c. Again, in each fermentative process the substance which is to undergo the fermentation must be susceptible of the particular fermentation: a substance that contains sugar can undergo the alcoholic fermentation, a substance that contains alcohol can undergo the acetic acid fermentation, &c. The same is the case in the infectious diseases: an individual must be susceptible to the disease, though it is not quite clearly established what the meaning of this is. Further: just as in the fermentative process the susceptibility of the substance alone is not sufficient, is only a preliminary condition, the actual infection with the specific microbe being the essential, so also in the infectious disease: in order that a susceptible individual should become the subject of the disease it is essential that the specific microbe should be present and should find entrance into this susceptible individual. Just as little as a particular condition of the atmosphere, of temperature, &c., is capable of producing the souring of milk, so also a particular atmospheric or telluric condition, season, or other external circumstances alone cannot produce an infectious disease. What is wanted in the first place is the presence of the bacterium lactis in the one, the specific pathogenic microbe in the other; atmospheric or telluric conditions may and do favour the more rapid multiplication and dissemination of the bacterium lactis or other specific microbes, but without the presence of the specific microbes these processes could not take place. "Thunder in the air" could not turn the milk sour, could not make meat tainted, could not turn beer or wine sour, without the presence of the specific microbes, which by their presence and multiplication produce those undesired changes in these substances; the particular condition of the air could and would increase their rate of multiplication and distribution, and therefore increase the chances of infection of these substances and therefore a more conspicuous manifestation of the effects of the activity of those microbes, but it could not produce the microbes themselves.

Pathogenic Bacteria.

The different pathogenic bacteria connected with and causing the different infectious diseases have then the power of growing and multiplying within the infected individual and through the different poisonous substances—toxins—which they therein produce, of causing the changes which characterise the particular disease.

I show you here photographs of a variety of such pathogenic bacteria, and you will see from them that both as regards the manner of distribution of these bacteria in the tissues of the infected individuals as also in their morphological and biological characters in artificial cultures, most of them are sufficiently distinguished from one another and from other non-pathogenie bacteria. In considering the general action of pathogenic bacteria we find that they may be grouped into (*a*) such as are entirely, so far as our knowledge at present goes, dependent on the living body of man or animals; these are endogenic bacteria or true parasites, for they do not appear to lead an existence independent of the living body: when, therefore, infection by them takes place, it takes place by direct transference from an infected individual to a new one; this is so in small-pox, in vaccinia, and in hydrophobia; (*b*) a second group comprises those which are capable besides a parasitic life, *i.e.* growing and multiplying within the animal body, to lead also an existence independent of the animal body; that is to say, they, like many other non-pathogenic bacteria, are capable of thriving in suitable materials in the outside world; such are anthrax and fowl cholera, asiatic cholera and typhoid fever, tetanus and diphtheria, and others. But also amongst these some can lead such an "ectogenic" life comparatively easily, while others do so only in a restricted sense; while, for instance, anthrax, tetanus, typhoid fever can lead such ectogenic life easily, *i.e.* growing and multiplying outside the animal body; others, like tubercle and glanders, do so only to a very small extent. The former are obviously the more dangerous to man and animals on account of their more ready distribution than the latter, of which the ectogenic existence is considerably restricted by various conditions, *e.g.* they require higher temperatures to grow at, they require a much more specialised nutritive medium than is generally attainable by them.

Time does not permit me to show you in detail the many and wonderful results obtained within a comparatively short recent period by a large number of workers, as regards the identification of many of the pathogenic bacteria, their habits of life, their mode of spread and infection; the way in which their action can be attenuated, their effects weakened, and such weakened cultures used for protective inoculations; the brilliant results achieved by Pasteur and many others in these protective and curative inoculations against anthrax, against fowl cholera, against tubercle, against hydrophobia, against tetanus and other diseases. But I will ask you to bear in mind that almost the entire study of bacteria, the exact methods first introduced by Koch and now universally used not only in regard to pathogenic bacteria, but in all other branches of bacteriology; the exact knowledge that we possess of some of the most important branches of hygiene: as the knowledge of the exact nature of contagium, its mode of spread, the means of disinfection, the methods of protective inoculation, and a hundred and one other important points have been the result of, and gained by, experiment on animals. Amongst the wilderness of misery, cruelty, and death inflicted by mankind on animals for gain, for sport, pleasure, and other similar objects, to decry, as some do, the use of a comparatively few animals for the sake of gaining knowledge of the most important and complex phenomena of life and of disease, and of securing power to apply this knowledge in the interest not only of mankind, but of the animals themselves, is apt to make one remember the words: "Ye blind guides! which strain at a gnat and swallow a camel," or the words, "Thou hypocrite! cast out first the beam out of thine own eye, and then shalt thou see clearly to pull out the mote that is in thy brother's eye."

SURGERY AND SUPERSTITION.

TO those unversed in the history of surgery it may come as a surprise that many of the appliances commonly regarded as the inventions of yesterday, are but the perfected forms of implements long in use. It is astonishing to find amongst the small bronzes of the National Museum at Naples, bistouries, forceps, cupping-vessels, trochars for tapping, bi-valvular and tri-valvular specula, an elevator for raising depressed portions of the skull, and other instruments of advanced construction which differ but little from their modern congeners. The invention of such instruments, and the skill displayed in their construction, presupposes a long period of surgical practice. We find, accordingly, that four hundred years before our era, Hippocrates was performing numerous operations bold to the verge of recklessness. Thus he was accustomed to employ the trepan not only in depression of the skull or for similar accidents, but also in cases of headache and other affections to which, according to our ideas, the process was singularly inapplicable. Strangely enough, the Montenegrins are, or recently were, accustomed to get themselves trepanned for similar trifling ailments, and it is probable that in both instances the procedure was but the surviving custom of primeval ages. That such operations were then performed Dr. Robert Munro, in his admirable article upon prehistoric trepanning in the February number of the *Fortnightly Review*, conclusively shows. His paper records a strange blending of the sciences of medicine and theology in their initial stages; for, whilst he makes it clear that during the neolithic period a surgical operation was practised (chiefly on children) which consisted in making an opening through the skull for the treatment of certain internal maladies, he renders it equally evident that the skulls of those individuals who survived the ordeal were considered as possessed of particular mystic properties. And he shows that when such individuals died fragments were often cut from their skulls, which were used as amulets, a preference being given to such as were cut from the margin of the cicatrised opening. The discovery arose as follows. In the year 1873 Dr. Prunières exhibited to the French Association for the Advancement of Science an oval cut from a human parietal bone, which he had discovered in a dolmen near Marvejols, embedded in a skull to which it had not originally belonged. His suggestion that it was an amulet was confirmed on the discovery of similar fragments of bone grooved or perforated to facilitate suspension. When Dr. Prunières's collection was examined by Dr. Paul Broca he pointed out that that portion of the margin of the bone which had been described as "polished" owed its texture to cicatricial deposits in the living body, and that, where these were wanting, death had ensued before the pathological action was set up, or the operation had been *post mortem*.

These discoveries led to widespread investigation, and to the production of trepanned skulls from Peru, from North America, and from nearly every country of Europe. These were not restricted to any particular race or period, but ranged from the earliest neolithic age to historic times, and included skulls of dolichocephalic and brachycephalic types.

The method of conducting the operation appears to have been to gradually scrape the skull with a sharp flint, though there is occasional evidence of its use in a sawing manner such as obtained when the ruder implement was superseded by one of metal. The process was almost exclusively practised upon children, probably on account of the facility with which it could then be accomplished, and possibly also as an early precaution against those evils for which it was esteemed a prophylactic. What the dreaded evils were was suggested by Dr. Broca, who, whilst he believed that the operation was primarily conducted for therapeutic purposes, saw behind these the apprehension of a supernatural or demoniacal influence. Readers of Lenormant's "Chaldean Magic" will remember "the wicked demon which seizes the body, which disturbs the body," and that "the disease of the forehead proceeds from the infernal regions, it is come from the dwelling of the lord of the abyss." With such an antiquated record before us it is, therefore, by no means an extravagant theory to broach, as Dr. Broca has done, that many of the convulsions of childhood, which disappear in adult life, were regarded as the result of demoniacal possession. This being granted, what more natural than to assist the escape of the imprisoned spirit by boring a hole in the skull which formed his prison. When a patient survived the operation he became a living witness to the conquest of a fiend, and it is comprehensible that a fragment of his skull taken after death from the very aperture which had furnished the exit would constitute a powerful talisman. Chaldean demons, as we know, fled from representatives of their own hideous forms, and, if they were so sensitive on the score of personal appearance, others may have dreaded with equal keenness the tangible record of a previous defeat. It is certain that to cranial bones medicinal properties were ascribed, a belief in the efficacy of which persisted to the dawn of the eighteenth century; whilst, in recent years, such osseous relics were worn by aged Italians as charms against epilepsy and other nervous diseases. When once the dogma was promulgated that sanctity and a perforated skull were correlated, fond relatives might bore the heads of the departed to facilitate the exodus of any malignant influence still lingering within, and to ensure them, by the venerated aperture, a satisfactory position in their new existence. For similar reasons the bone amulet was buried with the deceased, and sometimes it was even placed within his skull. Dr. Munro considers it hard to say for what purpose such an insertion should have been made, but, arguing from his data, the practice does not appear to me difficult of explanation. He has shown that disease was the work of a demon imprisoned in the skull; that this demon was expelled through the trepanned hole; and that its margins were thus sanctified for talismanic purposes. The unclean spirit was gone out of the man, and observation showed that, during the man's earthly existence, he did not return; but what guarantee was there that in the dim unknown region to which the deceased was passing the assaults of the evil one might not be renewed, that he might not return to his house whence he came out, and, with or without other spirits more wicked than himself, enter in and dwell in the swept and garnished abode? Surely, with such a possibility before them, it was the duty of pious mourners to offer all the protection that religion could suggest, and to defend the citadel with that potent amulet which recorded the previous discomforture of the besieger. The *post mortem* trepanning may have been such a pious endeavour to carry sacramental benefits beyond the grave, as induced the early Christians to be baptised for the dead, and, if there be truth in the deductions which have been made from the evidence, they point not only to a belief in the supernatural and in the existence of a future state, but also to that pathetic struggle of human love to penetrate the kingdom of death, which has persisted from the death of "Cain, the first male child, to him that did but yesterday suspire."

The possibility of reasonably making such deductions from a few decayed bones is a remarkable proof of the progress of anthropological science. Should any readers regard these deductions as unwarranted, they must remember that their value is dependent upon a series of facts which can here only be but very imperfectly reproduced. For these evidences in full sequence reference should be made to the paper by Dr. Munro, which forms the subject of this notice, and which will amply repay perusal. FRANK REDE FOWKE.

ANIMAL HEAT AND PHYSIOLOGICAL CALORIMETRY.[1]

THE problem of animal heat is one of the oldest problems of scientific speculation. Nevertheless it is only within recent years that we have been able to speak of it in terms of modern knowledge.

Among the earliest contributors to such knowledge we may cite John Mayow and Joseph Black. Mayow was the first to suggest that atmospheric air is not a simple element and that its "nitro-aeric particles," in combining with the blood in the lungs, produce the animal heat, while Black demonstrated that the air expired by the lungs contains "fixed air" or, as we now call it, carbonic acid.

Priestley discovered oxygen gas in 1771, but Lavoisier was the first to show that this constituent of the air is taken in by the blood in the lungs, and that its combination with the carbon, which is a regular constituent of all organic matter, produces animal heat in the same way as in all combustions. Lavoisier was the first, too, who measured the heat produced by an animal, making use of the ice calorimeter, constructed by himself and Laplace, while Crawford nearly at the same time made investigations with an apparatus similar to our water calorimeter.

Neither form of apparatus is very suitable for this purpose. Scharling, Vogel, and Hirn made use of an air calorimeter. Within the last few years Prof. d'Arsonval of Paris adopted the same principle, and I myself have worked out the theory of it, and constructed apparatus, with which I have made a great number of experiments.

The animal to be experimented upon in my apparatus is placed in a chamber surrounded by double metallic walls. The heat given out by the animal raises the temperature of the air contained between the walls, until the radiation from the outer surface causes a loss of heat equal to the amount gained by it from the animal. This state of things having been established, the temperature of the air becomes constant, the gain and loss of heat being equal. In this way the heat given out can be calculated.[1]

The chamber containing the animal is well ventilated by aspiration. If we measure the volume of the air aspired and conduct a part of it through liquids absorbing carbonic acid, the amount of this gas given out by the animal can be measured. In another series of experiments the amount of oxygen absorbed by the animal was also measured. The combination of apparatus I made use of for this purpose is a variation of the method invented by Regnault and Reiset.

I shall not weary you with a long enumeration of all my experiments. All I wish is to give a brief account of some of the results, which I think are of interest from a general biological point of view.

In the first place, I may mention my experiments on fever. The high temperature in cases of febrile disease—is it the result of greater heat production? Are we to assume that certain poisons taken into the body, or produced in it by microbes, stimulate the nervous system, or directly influence the tissues in such a way as to cause greater oxidation, and thus to produce more heat?

That is the opinion of many medical men, but it is met with the great difficulty that neither the expiration of carbonic acid nor the excretion of oxidized nitrogenous matter is increased to such a degree as to account fully for the rise of temperature. Therefore Traube, the late clinician of Berlin, proposed the theory that the rise of temperature in fever is caused, not by greater heat production, but by greater retention of heat.

On producing fever in animals by injection of various putrid substances, I found that at the beginning of the fever, heat production is not increased, that the loss of heat is diminished, and that the difference between the normal loss and that observed in the period of rising temperature is sufficient to cause the febrile rise. When the temperature reaches its highest point the amount of heat given out rises and comes to its *normal* rate. Finally, when the fever begins to subside, during the period of falling temperature, the loss of heat is greatly increased.

All this is in perfect accordance with Traube's theory. Nevertheless, I cannot say that heat production is *never* augmented in fever. I have not yet been able to make many experiments on man. There are two great difficulties in the way, and the greatest is the impossibility of making a strict comparison between the heat production in fever and that in the normal state, except in cases of the regular intermittent type. Malaria, once so frequent in several parts of Germany, nowadays, thanks to hygienic improvements, is very seldom met with. So I have been able to make only two experiments on an individual afflicted with intermittent fever, some on invalids with abdominal typhus (typhoid fever), some on cases of pneumonia, and others on cases of fever caused by the injection of Koch's tuberculine during the short time when such injections were practised in the hospitals of Erlangen. In these cases I found a small but real augmentation of heat production, and therefore I am inclined to suppose that the question is not yet solved. Perhaps there are two causes able to raise the temperature in fever, one of them prevailing in some cases or types of fever.

Most of my studies were conducted with a view to explain the connection between heat production and other physiological functions, and the influence of external circumstances on it. Higher animals, mammals and birds, maintain their own temperature nearly at the same degree, even when the temperature of the surrounding air changes within large limits. Is this *regulation*, as we call it, caused by adaptation of heat production to the greater or smaller loss, or are there means to keep the loss constant in spite of the changing difference between the animal and surrounding objects?

On measuring the heat production of the same animal in cold and warm air, I found that it is smallest in air of medium temperature, *i.e.* about 15° C., becoming greater in lower and in higher temperatures. Thus an animal produces and loses nearly the same amount of heat in air at 5° as in air at 25°. In this case regulation of the animal temperature can be effected only by changes of the co-efficient of emission of heat from the skin, caused by changes of circulation. But for longer periods

[1] Paper by Prof. Rosenthal of Erlangen, read before the Biological Section at the Edinburgh meeting of the British Association for the Advancement of Science.

[1] For a fuller account see my papers in: *Archiv für Physiologie*, 1889, and in *Sitzungsber. d. K. preuss.* Akad. d. Wissensch. 1888-1892.

that regulation is insufficient. In winter time we use thicker clothing, we need more food, and if the cold is very great, we produce more heat by muscular action. In accordance with that experience, I found that animals produce more heat in winter than in summer. If nourished with the same food, sufficient to maintain their weight constant in winter, they do not oxidize the whole in summer, and therefore they gain in weight. It is remarkable that similar changes were observed by Dr. Karl Theodor, Duke of Bavaria, in the amount of carbonic acid expired by a cat, in the case of which he measured the expiration of this gas during five months.

Many experiments have been made to find the combustion heat of our food-stuffs. For want of direct animal calorimetry, physiologists used these data for calculating the heat produced by living beings; but as my experiments show, there is frequently no exact accordance between the two.

Richly nourished animals produce less, sparely nourished ones more, heat than the calculation gives. Between the two cases there is a third one in animals *sufficiently* nourished, viz. such as take in so much nutriment as serves to maintain their weight unchanged for a long time. In this case only the amount of heat produced is really equal to that calculated upon the combustion of the constituents of food. But also in this case variations are observed, caused by change of temperature, muscular motion or other circumstances, so that only the middle figures correspond exactly to the theoretical value.

Thus, if a well-nourished animal is starved the heat production remains unchanged from three to four days, the animal burning its stored-up materials and losing much of its weight; only then is it suddenly reduced to a lower amount. If now food is given again, heat production remains small, the weight increases, and then, three or four days later, the heat production increases and reaches its former amount.

If a sufficiently nourished animal takes in all its food once a day, the heat production varies very regularly in the twenty-four hours. Two hours after the meal it begins to rise, comes to its maximum point between the fifth and seventh hour, falls suddenly between the eleventh and twelfth hour. In the second half of the period the changes are small, the minimum point being usually in the twenty-third hour.

Similar changes go on in the expiration of carbonic acid. But after the meal it rises much more rapidly, and therefore comes earlier to its maximum point. Thus the ratio between heat production and expiration of carbonic acid is not a constant. This is true not only in the daily period. The variations are seen to be still greater when we compare different animals, or the same animal at different times and in different states of nutrition.

By such researches we are enabled to examine more exactly what chemical changes are going on in the animal system. The materials afforded by food are all oxidized at last, and leave the body in the form of carbonic acid and nitrogenous matter like urea. What in a longer period is burnt in such a way, we can, with a certain degree of exactness, make out by chemical examination of the constituents of food on the one hand, and of the excretions on the other. We can make up, in such a way, a balance account for gain and loss of the animal, like the balance account of a merchant. But such an account gives no exact knowledge, because we have no means of completing it by taking an inventory. We are, as regards the living body, in the same position as a political economist, who knows the amount of goods imported into and exported out of a country, but does not know what has become of the goods stored up or used up in the country itself. Therefore political economists do not now regard the mere balance of trade as being so important as they formerly thought.

Physiology, like all branches of science, begins with a mere description of processes observed. With the progress of our knowledge, reason tries to connect these processes one with another, and with those going on in lifeless nature. What we call *understanding* is nothing else than knowing such connections. Now in the case of bodily income and expenditure, it is easy to observe that all materials going out of the system are more oxidized than those taken in as food, and reason tells us that the combination of these food materials with the oxygen inspired must be the source of animal heat. Hence, we have no doubt that the amount of heat produced must correspond to the amount of chemical processes going on during the same time. But these processes we cannot observe directly; we can only observe the final products carbonic acids and others, when they leave the body. But by some of the processes heat may be produced or absorbed without any visible change of the body as a whole, viz. by solution of solid matter, by splitting highly complex substances into more simple ones, by forming sugar out of starch or glycogen out of sugar. Considering this, we need not wonder that for a long time it was impossible to answer the question whether there is any other source of heat production in animals besides oxidation. Only long continued calorimetric measurements have enabled me to fill up this gap.[1] This done, I thought it possible to discover also something about these inner processes, by comparing, hour for hour, the heat production with the excretion of carbonic acid, and with the absorption of oxygen.

If the ratio between the heat produced and the carbonic acid expired changes, this cannot be explained otherwise than by the fact that different chemical substances are burned. Each substance, according to its chemical constitution, gives out, when oxidized, a certain amount of carbonic acid, and produces a certain amount of heat. But in the system it is a mixture of different substances which come to be oxidized. This mixture changes, not only in animals differently nourished, but also in the same animal in different periods of digestion. After a rich meal, what comes into the circulation first must be that part of the food that is easily and rapidly digested and easily and rapidly absorbed. Such substances are the proteid matters. Later, the other constituents of the food, especially fat, come to the tissues, where they are burned. Now *fats*, for the same amount of carbonic acid, produce far more heat than proteids; so, during the first hours of digestion the afflux of oxidizable matter to the tissues being very great, both heat production and expiration of carbonic acid increase, but the latter in a far higher degree than the former.

The animal body may be compared, as Prof. Huxley so well says, to an eddy in a river, which may retain its shape for an indefinite length of time, though no one particle of the water remains in it for more than a brief period. But there is not only the difference between the animal eddy and the eddy of the river, viz. that the matter which flows into it has a different chemical composition from the matter which flows out of it, but in addition, matters which make up the eddy in a given time, change, if I may so say, their chemical value, combine with or separate from each other, without any visible change of the whole system.

The study of heat production is of the greatest value. No doubt, the study of the vital processes becomes more complicated when we take into account the invisible internal changes occurring in the body. But simplicity is not the highest aim in scientific inquiries; the highest possible exactness is that to which we must aspire. Happily, the history of science shows that after trying several ways to solve complex problems, we find that one of them leads to a higher point of view, whence things appear in all their completeness, simplicity and distinctness. Towards such a point of view my researches are but the first step. Let us hope that the united forces of many physiologists will shorten the time necessary for the completion of the work.

MAGNETIC PROPERTIES OF LIQUID OXYGEN.[2]

AFTER alluding to the generous aid which he had received both from the Royal Institution and from others in connection with his researches on the properties of liquid oxygen, and to the untiring assistance rendered him by his co-workers in the laboratory, Prof. Dewar said that on the occasion of the commemoration of the centenary of the birth of Michael Faraday he had demonstrated some of the properties of liquid oxygen. He hoped that evening to go several steps further, and to show liquid air, and to render visible some of its more extraordinary properties.

The apparatus employed consisted of the gas-engine down stairs, which was driving two compressors. The chamber containing the oxygen to be liquefied was surrounded by two circuits, one traversed by ethylene, the other by nitrous oxide. Some liquid ethylene was admitted to the chamber belonging to its circuit, and there evaporated. It was then returned to the

[1] See also my address delivered to the general meeting of the German Association of Naturalists at Bremen, 1890.

[2] Abstract of Friday evening discourse delivered at the Royal Institution by Prof. Dewar, F.R.S.

compressor as gas and liquefied, and thence, again, into the chamber as required. A similar cycle of operations was carried out with the nitrous oxide. There was a hundredweight of liquid ethylene prepared for the experiment. Ethylene was obtained from alcohol by the action of strong sulphuric acid. Its manufacture was exceedingly difficult, because dangerous, and as the efficiency of the process only amounted to 15 or 20 per cent. the preparation of a hundredweight of liquid was no light task. The cycle of operations, which, for want of time, was not fully explained, was the same as that commonly employed in refrigerating machinery working with ether or ammonia.

The lecturer then exhibited to the audience a pint of liquid oxygen, which by its cloudy appearance showed that it contained traces of impurity. The oxygen was filtered, and then appeared as a clear transparent liquid with a slightly blue tinge. The density of oxygen gas at − 182° C. is normal, and the latent heat of volatilisation of the liquid is about 80 units. The capillarity of liquid oxygen at its boiling-point was about one-sixth that of water. The temperature of liquid oxygen at atmospheric pressure, determined by the specific heat method, using platinum and silver, was − 180° C.

Reference was then made to a remarkable experimental corroboration of the correctness for exceedingly low temperatures of Lord Kelvin and Prof. Tait's thermo-electric diagram. If the lines of copper and platinum were prolonged in the direction of negative temperature, they would intersect at − 95° C. Similarly, the copper and palladium lines would cut one another at − 170° C. Now, if this diagram were correct, the E.M.F. of the thermo-electric junctions of these two pairs of metals should reverse at these points. A Cu − Pt junction connected to a reflecting galvanometer was then placed in oxygen vapour and cooled down. At − 100° C. the spot of light stopped and reversed. A Cu − Pd junction was afterwards placed in a tube containing liquid oxygen, and a similar reversal took place at about − 170° C.

Liquid oxygen is a non-conductor of electricity: a spark taken from an induction coil, one millimetre long in the liquid requires a potential equal to a striking distance in air of 25 millimetres. It gave a flash now and then, when a bubble of the oxygen vapour in the boiling liquid came between the terminals. Thus liquid oxygen is a high insulator. When the spark is taken from a Wimshurst machine the oxygen appears to allow the passage of a discharge to take place with much greater ease. The spectrum of the spark taken in the liquid is a continuous one, showing all the absorption bands.

As to its absorption spectrum, the lines A and B of the solar spectrum are due to oxygen, and they came out strongly when the liquid was interposed in the path of the rays from the electric lamp. Both the liquid and the highly compressed gas show a series of five absorption bands, situated respectively in the orange, yellow, green, and blue of the spectrum.

Experiments prove that gaseous and liquid oxygen have substantially the same absorption spectra. This is a very noteworthy conclusion considering that no compound of oxygen, so far as is known, gives the absorptions of oxygen. The persistency of the absorption through the stages of gaseous condensation towards complete liquidity implies a persistency of molecular constitution which we should hardly have expected. The absorptions of the class to which A and B belong must be those most easily assumed by the diatomic molecules (O_2) of ordinary oxygen; whereas the diffuse bands above referred to, seeing they have intensities proportional to the square of the density of the gas, must depend on a change produced by compression. This may be brought about in two ways, either by the formation of more complex molecules, or by the constraint to which the molecules are subjected during their encounters with one another.

When the evaporation of liquid oxygen is accelerated by the action of a high expansion pump and an open test-tube is inserted into it, the tube begins to fill up with liquid atmospheric air, produced at the ordinary barometric pressure.

Dr. Janssen had recently been making prolonged and careful experiments on Mont Blanc, and he found that these oxygen lines disappeared more and more from the solar spectrum as he reached higher altitudes. The lines at all elevations come out more strongly when the sun is low, because the rays then have to traverse greater thicknesses of the earth's atmosphere.

Michael Faraday's experiments made in 1849 on the action of magnetism on gases opened up a new field of investigation. The following table, in which + means "magnetic" and − means "negative," summarises the results of Faraday's experiments.

Magnetic Relations of Gases (Faraday).

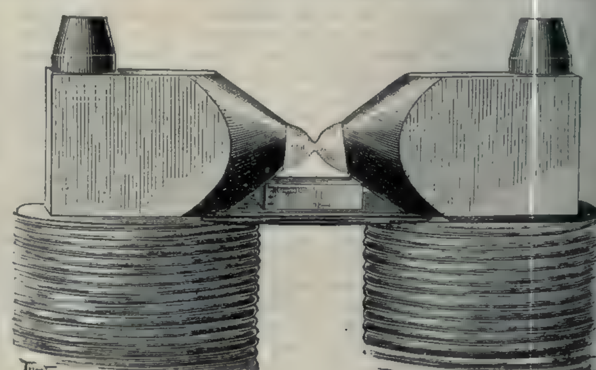
	In Air.	In Carbonic Acid.	In Hydrogen.	In Coal Gas.
Air	o	+	+ weak	+
Nitrogen	−	−	− strong	−
Oxygen	+	+	+ strong	+ strong
Carbonic acid ...		o	−	− weak
Carbonic oxide...	−	−	−	− weak
Nitric oxide ...	− weak	+	+	...
Ethylene ...	−	−	−	− weak
Ammonia ...	−	−	−	...
Hydrochloric acid	−	−	− weak	...

Becquerel was before Faraday in experimenting upon this subject. Becquerel allowed charcoal to absorb gases, and then examined the properties of such charcoal in the magnetic field. He thus discovered the magnetic properties of oxygen to be strong, even in relation to a solution of ferrous chloride, as set forth in the following table:—

Specific Magnetism, Equal Weights (Becquerel).

Iron	+	1,000,000
Oxygen...	+	377
Ferrous chloride solution, sp. gr. 1·4334	+	140
Air	+	88
Water	−	3

The lecturer took a cup made of rock salt, and put in it some liquid oxygen. The liquid did not wet rock salt, but remained in a spheroidal state. The cup and its contents were placed between and a little below the poles of an electro-magnet. Whenever the circuit was completed, the liquid oxygen rose from the cup and connected the two poles, as represented in the cut, which is copied from a photograph of the phenomenon. Then it boiled away, sometimes more on one pole than the other, and when the circuit was broken it fell off the pole in drops back into the cup. He also showed that the magnet would draw up liquid oxygen out of a tube. A test-tube containing



Magnetic ttraction of Liquid Oxygen.

liquid oxygen, when placed in the Hughes balance, produced no disturbing effect. The magnetic moment of liquid oxygen is about 1000 when the magnetic moment of iron is taken as 1,000,000. On cooling some bodies increased in magnetic power. Cotton wool, moistened with liquid oxygen, was strongly attracted by the magnet, and the liquid oxygen was actually sucked out of it on to the poles. A crystal of ferrous sulphate, similarly cooled, stuck to one of the poles.

The lecturer remarked that fluorine is so much like oxygen in its properties, that he ventured to predict that it will turn out to be a magnetic gas.

Nitrogen liquefies at a lower temperature than oxygen, and one would expect the oxygen to come down before the nitrogen when air is liquefied, as stated in some text-books, but unfortunately it is not true. They liquefy together. In evaporating, however, the nitrogen boils off before the oxygen. He poured two or three ounces of liquid air into a large test-tube, and a smouldering splinter of wood dipped into the mouth of the tube was not re-ignited; the bulk of the nitrogen was nearly five minutes in boiling off, after which a smouldering splinter dipped into the mouth of the test-tube burst into flame.

Between the poles of the magnet all the liquefied air went to the poles; there was no separation of the oxygen and nitrogen. Liquid air has the same high insulating power as liquid oxygen. The phenomena presented by liquefied gases present an unlimited field for investigation. At − 200° C. the molecules of oxygen had only one-half of their ordinary velocity, and had lost three-fourths of their energy. At such low temperatures they seemed to be drawing near what might be called "the death of matter," so far as chemical action was concerned; liquid oxygen, for instance, had no action upon a piece of phosphorus and potassium or sodium dropped into it; and once he thought, and publicly stated, that at such temperatures all chemical action ceased. That statement required some qualification, because a photographic plate placed in liquid oxygen could be acted upon by radiant energy, and at a temperature of − 200° C. was still sensitive to light.

Prof. M'Kendrick had tried the effect of these low temperatures upon the spores of microbic organisms, by submitting in sealed glass tubes blood, milk, flesh, and such-like substances, for one hour to a temperature of −182° C., and subsequently keeping them at blood heat for some days. The tubes on being opened were all putrid. Seeds also withstood the action of a similar amount of cold. He thought, therefore, that this experiment had proved the possibility of Lord Kelvin's suggestion, that life might have been brought to the newly-cooled earth upon a seed-bearing meteorite.

In concluding, the lecturer heartily thanked his two assistants, Mr. R. N. Lennox and Mr. J. W. Heath, for the arduous work they had had in preparing such elaborate demonstrations.

SCIENTIFIC SERIALS.

IN the *Journal of the Royal Agricultural Society of England* (third series, vol. iv. pt. 1) there is an interesting paper on the home produce, imports, consumption, and price of wheat over forty harvest years, 1852–3 to 1891–2, by Sir J. B. Lawes and Dr. J. H. Gilbert. This paper, extending to fifty-five pages, contains a general review of the produce of the experimental plots at Rothamsted, from which they have annually calculated the wheat crop of this country.—The first of the official reports is that of the Royal Veterinary College on investigations conducted for the Royal Agricultural Society during the year 1892. An interesting case of actinomycosis is related; a heifer with tongue badly diseased was put under Thomassen's treatment. Potassium iodide administered at first in doses of one drachm, twice daily, and the doses gradually increased to three drachms, effected a complete cure in about ten weeks.—Experiments have lately been made at the Veterinary College with Koch's tuberculin. The results in the case of seventy-two animals inoculated and afterwards killed show that "the tuberculin pointed out correctly the existence of tuberculosis in twenty-seven animals and wrongly in five, and it failed to indicate the existence of the disease in nineteen. In only three of the twenty-seven animals in which the tuberculin correctly pointed out the existence of tuberculosis could a positive diagnosis have been made by any other means." Experiments have also been made with Kalning's mallein, and "the results warrant the statement that mallein is an agent of greater precision than tuberculin, and that it is likely to render most important service in any attempt to stamp out glanders."

Wiedemann's Annalen der Physik und Chemie, No 4.—On electric discharges; the production of electric oscillations, and their relations to discharge tubes, by H. Ebert and E. Wiedemann. The influence of electric oscillations of given frequency in producing glow in vacuum tubes without electrodes was investigated by means of Lecher's wire system. The oscillations in the primary circuit were produced by means of an influence machine throughout. The terminals of the machine were connected to the primary condenser, consisting of four plates, to the further two of which the two Lecher wires, copper wires or thick metal tubes, were attached, running parallel for distances varying from 2 to 14 m., and ending in another condenser of variable capacity. The sensitive tubes were placed in various positions between or near the plates of the secondary condenser. It was found that wide tubes, not too short, glowed most readily. Nodes along the wires were discovered by means of wire bridges, which were moved along the wires until the tube glowed, or, if it was glowing already, until it reached a point where the glow became more intense and uniform. It was found that the position of the nodes was independent of the pressure in the tube, but that as evacuation proceeded the limits within which the tube would glow grew wider. Hence the most accurate method for finding the nodes, was by finding them for the highest possible pressure of gas in the tube.—On the comparison of intensities of light, by the photoelectric method, by J. Elster and H. Geitel. Apart from the dissipation of an electric charge from a negative zinc pole by ultra-violet radiation, it is also possible to measure the intensity of optically active light by an electric method. If a clean surface of potassium is joined to the negative pole of a battery, and a platinum or aluminium electrode to the positive pole, and the two electrodes are placed in a vacuum cell, the illumination of the potassium surface will allow a current to flow whose strength will be proportional to the intensity of the light source, and can be measured by means of a galvanometer. That this is really the case was proved by measuring independently in this way the intensities of two luminous sources, and then combining them, when the resultant reading was found to be equal to the sum of the other two, within the limits of constancy of the sources themselves. The greatest effect is produced by the blue rays.—Also papers by Messrs. Bjerknes, Zahn, Voigt, Richarz, Ambronn, Christiansen, Goldhammer, and Oberbeck.

Meteorologische Zeitschrift, March.—Iridescent clouds, by H. Mohn.—The paper contains observations made at Christiania during the years 1871-1892, together with a detailed investigation of the formulæ recently employed. During this period iridescent clouds were only visible on forty-two days; in some years the phenomenon failed entirely, and was not observed during the whole lustrum 1876-80. The great majority of cases occurred in December and January, but a few occurred in summer; the phenomenon was also seen somewhat more frequently at sunset than at sunrise or mid-day, but the difference is so small as to make it appear that its occurrence is independent of the time of day. The height of the clouds varied from about fourteen to more than eighty miles, the lower level being about twice the height at which ordinary cirrus clouds are usually seen at Christiania. The phenomenon appears to have some connection with the state of the weather, as an examination of the synoptic charts showed that it mostly occurred during the prevalence of stormy weather in the North Atlantic and over Northern Europe, and when the air was dry and warm at Christiania.—On the determination of wind force during gusts of a Bora storm, by E. Mazelle. From an investigation of the anemometer observations at Trieste for the ten years 1882-1891, the greatest hourly velocity recorded was seventy miles. But as hourly values give little idea of the violence of individual gusts, the author adapted an ingenious electrical arrangement to the anemometer, by which he could record the number of revolutions of the cups in each second. During a storm on January 16 last, the gusts during the space of a few seconds reached the velocity equivalent to 100 to 140 miles an hour. Presuming the instrument to have been a large-sized anemometer, this high velocity is not unlikely, as in a paper read before the Royal Meteorological Society on May 18, 1881, by R. H. Curtis, a velocity at the rate of 120 miles an hour at Aberdeen is quoted as recorded in gusts lasting two minutes, while shorter intervals, if they could be measured, would no doubt show higher velocities; and at Sydney a velocity of 153 miles an hour was recorded during one or two minutes. In all these cases the factor 3 has been used for the ratio of the movement of the cups to that of the wind, but this factor has been shown to give a velocity which is nearly 30 per cent. too high.

Bulletin de la Société des Naturalistes de Moscou, 1892.—(No. 1.) The chief papers are:—The development of the gemmulæ in *Ephydatia fluviatilis*, by W. Zykoff.—Catalogue of Kazan Lepidoptera, continued, by L. Kroulikovsky.—Analogy between the solution of a gas and of a salt in indifferent solutions of salts, by I. M. Syetchenoff. The author's law, which was found or carbon dioxide $\left(y = ae - \frac{k}{x}\right)$, holds good within certain limits, for the solution of salts in the same solutions; but the latter must only be taken either weak or of medium strength.—New plants and insects from Sarepta, by Alex. Becker.—On a mesozoic fish from the Altai, by J. V. Rohon (*Lepidotus altaicus*, n. sp.).—On the cells of some conjugata devoid of nucleus, by J. Gerasimoff.—(No. 2.) The Rhinoceridæ of Russia, and the development of Rhinoceridæ, by Marie Pawloff. —Researches relating to some Protococcoidæ, by Al. Artari (in German). The work has been done chiefly in order to study the doubtful species. They were cultivated in different conditions, and proved to be independent species. At the same time the author experimented upon the influence of various media upon variations; the latter proved to occur within certain well-defined limits only, not exceeding the specific differences. The Algæ, when returned to their previous conditions, may return to their previous forms, thus proving a certain resistance of the organism against the medium. The following new species are described:—*Glœocystia nægeliana*, *Pleurococcus simplex*, *P. conglomeratus*, *P. regularis*, *P. Beyerinckii*, and *Chlamydomonas apiocystiformis* (three plates).—The birds of the Government of Moscow, by Th. Lorenz, with preface by Prof. Menzbier (first paper). Eighty-eight species are mentioned, with remarks upon their manners of life, based upon many years' observations.

Zapiski (*Memoirs*) *of the Novoros Sian* (*Odessa*) *Society of Naturalists*, vol. xvii. 2.—N. Andrussoff contributes, under the name of bio-geographical notes, a paper on pelagic diatoms, which contains a list of all named species of diatoms which have hitherto been found, either free, or in the stomachs of pelagic animals, both near to the coasts and in the open sea. The list is based on the researches of Hooker, Ehrenberg, Baddeley, Grunow, Castracane, and so on, down to the *Challenger* expedition, and the works of Murray, Hensen, and Brun, and it is followed by short remarks upon the geological importance of diatoms. The paper is summed up in German. —Prof. Sintsoff gives a list of Neogene fossils in Bessarabia, the following species being new:—*Acmæa* (*Scurria*) *Reussi*, *tennissima*, *subrostata*, and *striato-costata*, *Acmæa pseudolævigata*, and *Buccinum subspinosum*.—D. Zabolotny discusses animal phosphorescence, and gives some facts on the same phenomenon observed in *limans*, near Odessa. The phosphorescent water was of a brown red colour, and contained masses of Daphniæ, Rotifers, and Infusoriæ. It appeared that luminosity was due to one Cilioflagellate, *Glenodinium*, from the *Peridinidæ* tribe, and it seems that light was emitted by the protoplasm itself of the little animal.—A. Lebedintseff describes the bathometer used in 1891 and 1892 during the explorations of the Black Sea; and G. Muskatblüth gives a note on mitotic division of leucocytes in circulating blood.

Annalen des K. K. Naturhistorischen Hofmuseums, viii. No. 1. (Wien, 1893.)—Dr. O. Finsch continues his "Ethnological experiences and authenticated objects from the South Sea." The present is the first paper on Micronesia, and deals with the Gilbert Islands. As is usual with Dr. Finsch's papers, it is well illustrated by eight plates, two of which are in colours, containing 110 figures, besides 16 wood-cuts. Although this paper, like the others of the series, is a catalogue of the objects collected by Dr. Finsch, and now in the National Museum in Vienna, it is at the same time an important contribution to the ethnography of Micronesia, a region of the great ocean about which comparatively little is known. The Gilbert Archipelago—often called the Kingsmill Islands—are best known to the frequenters of museums as the country of formidable weapons armed with serried rows of sharks' teeth, and of the coir armour which was worn as a defence against these deadly weapons. Dr. Finsch is of opinion that the Gilbert Archipelago, with Banaba and Nawodo, constitute a well-marked sub-province, as there is a distinct language, peculiar pantomimic dances (in which both sexes participate), characteristic tattooing, a special style of house, which latter are grouped into large villages, colossal assembly houses, well-built canoes, even for the South Sea, shark-tooth weapons, armour, a noose for catching eels, &c. He concludes by saying, "In every respect the Gilberts exhibit more affinity with Melanesia than with Polynesia, and least of all with Micronesia." The other articles are: "Characterless birds' eggs: an oological study" [on *Corvus corone*, *C. cornix* and *C. frugilegus*], by Emil C. F. Rzehak; "On the crystalline structure of meteoric iron," by G. Linck, and the usual official reports for 1892.

THE last three numbers received (2-4) of the *Bullettino della Società Botanica Italiana* contain a very large number of papers on the flora, phanerogamic and cryptogamic, of various districts of Italy and the adjacent countries, including an interesting note on the very rich flora of Monte Nerone. In addition to these Prof. R. F. Solla describes a case of polyembryony in the carob, *Ceratonia siliqua*, and also the structure of the tanniferous cells in the same plant. Sig. E. Baroni has a note on the relationship of calcicolous lichens to their substratum. Dr. C. Massalongo describes a gall on the bay, *Laurus nobilis*, due to the attacks of an insect which he regards as a new species, and names *Phytoptus Malpighianus*. Prof. G. Arcangeli gives the result of observations on the growth of the leaf-stalk of various species of Nymphæaceæ, which he finds to be greater in the case of immersed than of floating leaves. This he attributes to the vertical pressure of the water on the upper surface of the leaves in the former case. A paper by the late Prof. F. Pasquale was read, describing a fall of rain from lime-trees, quite unconnected with the manna produced by aphides, and due to the inability of transpiration to eliminate the whole of the water absorbed through the roots.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 23.—"Preliminary Notice on the Arrow-Poison of the WaNyika and other Tribes of East Equatorial Africa, with special reference to the Chemical Properties and Pharmacological Action of the Wood from which it is prepared." By Thomas R. Fraser, M.D., F.R.S., Professor of Materia Medica in the University of Edinburgh, and Joseph Tillie, M.D. (Edin.)

Burton,[1] Cameron,[2] and other travellers have given accounts of much interest of an arrow-poison used in warfare and in the chase by the WaNyika, WaKamba, WaGyriama, and other tribes of Eastern Equatorial Africa.

Several years ago, an opportunity was given to one of the authors to examine poisoned arrows, and the poison used in smearing them, of the WaNyika tribe. While the pharmacological action of this poison was found to have a close resemblance to that of *Strophanthus* seeds, its physical and chemical properties enabled the conclusions to be drawn that the poison was not made from these seeds, but was chiefly composed of an extract prepared from a wood.[3]

These conclusions have been confirmed by the examination of further specimens of the WaNyika arrow-poison, and of the wood from which it is prepared; and some of the results of this examination are stated in this paper.

The authors have separated from the arrow-poison and from the wood a crystalline glucoside, whose elementary composition, reactions and other characters they describe.

They have elaborately investigated the pharmacological action of this glucoside. The minimum-lethal dose for frogs was found to be about 0·00005 grain per 100 grains of weight of frog, and for rabbits about 0·000035 grain per pound of weight of animal.

The glucoside has a very pronounced action upon the heart. A large dose causes, in the frog, arrest of the contractions in a state of ventricular systole, and the heart soon afterwards acquires an acid reaction. After the heart is paralysed, respiration may continue for so long as an hour, and for a considerable time the frog can jump about actively. Smaller doses, on the other hand, slow the heart by prolonging diastole, and arrest its pulsations in a state of ventricular diastole. This diastolic arrest is not prevented by the administration of atropine, and is probably due to a direct action on the motor ganglia and muscle of the heart. The action on blood vessels is very slight. Transfusion experiments in the frog with a solution of 1 in 10,000 of saline produced only about the same effect as the pure saline solution alone.

A marked paralysing action is exerted upon the skeletal muscles, which also quickly pass into a condition of *rigor mortis*. The spinal cord and sensory and motor nerves are but little affected, and the former only doubtfully, except indirectly through the enfeebled circulation when large doses are administered. In warm-blooded animals, artificial respiration does not prevent death from cardiac failure.

In blood-pressure experiments, non-lethal doses were found to produce a remarkable slowing of the pulse, the vertical height of each pulse-curve indicating, at the same time, a great increase in the force of the ventricular contractions.

2 "Across Africa", 1885, p. 59.
3 Fraser, "On *Strophanthus hispidus*: its Natural History, Chemistry, and Pharmacology," "Edinburgh Roy. Soc. Trans.," vol. 35, Part IV, 1890, pp. 966-67.

The action upon the circulatory, muscular and nervous systems, therefore, closely resembles of that strophanthin.

April 27.—"The Electric Organ of the Skate. Note on an Electric Centre in the Spinal Cord." By J. C. Ewart, M.D., Regius Professor of Natural History, University of Edinburgh. Communicated by Prof. Sir W. Turner, F.R.S.

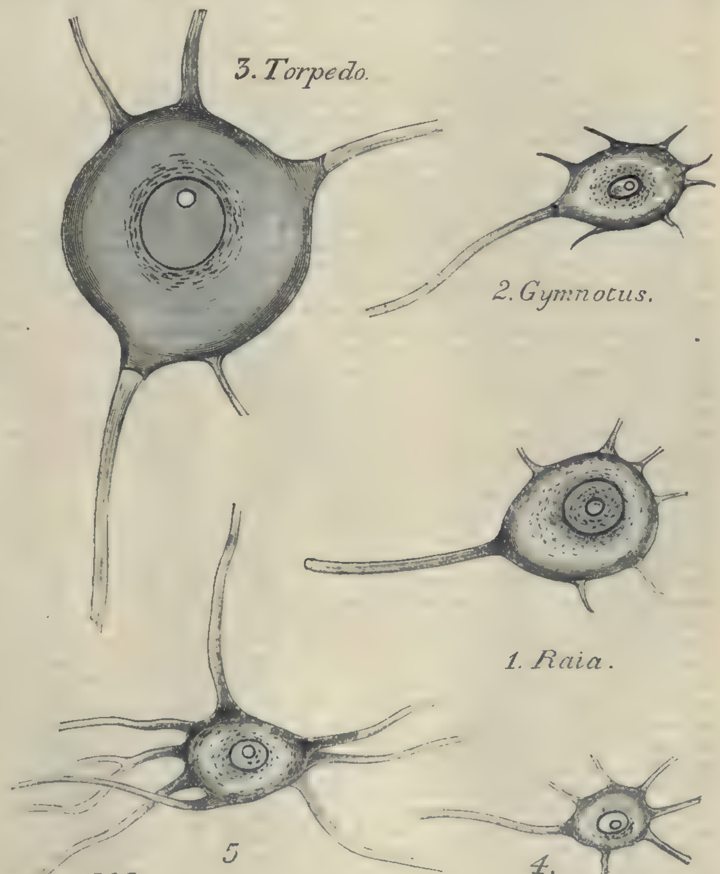
Having considered the development and structure of the electric organ of the Skate, it appeared to me desirable, by way of making my work more complete, to reinvestigate the nervous apparatus of the organ, and more especially to ascertain whether, as in *Torpedo* and *Gymnotus*, there is an electric centre. In *Torpedo* the electric organs are developed from a limited number of myotomes, and innervated by afferent fibres, belonging to a limited number of cranial nerves, which proceed from two large collections of cells—the electric lobes—situated in the region of the medulla. In *Gymnotus* the nerves for the electric organs proceed from two well-marked cellular tracts which extend along the greater length of the spinal cord, one at each side of the central canal. In the case of the Skate the question at the outset is, granting the existence of an electric centre, is it, as in *Torpedo*, situated in the brain or, as in *Gymnotus*, in the spinal cord? Sanderson and Gotch (*Journal of Physiology*, vol. x. No. 4), made out that in the Skate "a reflex centre is situated in the optic lobes," but, notwithstanding this, these lobes in the Skate in no way differ histologically from the corresponding structures in *Acanthias* and other Selachians unprovided with electrical organs.

The development of the Skate's organ from portions of the caudal myotomes, and its innervation by afferent fibres from certain caudal nerves, point to the electric centre being situated in the spinal cord rather than in the brain, and to its being, as in *Gymnotus*, on a level, and all but coextensive, with the electric organ.

Having observed, when working at the development of the electric organ, a number of large nerve-cells in the caudal portion of the spinal cord, the sections of Skate embryos made some years ago were first examined. It soon became evident that in sections from the middle of the tail on a level with the electric organ certain cells of the anterior horn of the cord were very much larger than in sections through the root of the tail, and further that in late embryos and very young Skate there was an electric centre, resembling in many respects the electric centre in *Gymnotus*.

It did not, of course, follow that the electric nerve-cells persisted into adult life. They might degenerate, and thus the supposed feebleness of the Skate's organ might be accounted for. The fact that the Skate's organ increases in size as the fish grows larger led me, however, to expect that large nerve-cells would be found in the caudal region of the spinal cord in well-grown fish. In this I was not disappointed, for, though there was at first some difficulty in demonstrating the presence of electric nerve-cells in large fish, on obtaining perfectly fresh material their position, size, and relations were easily made out, and the remarkable difference in the appearance of sections of the cord at, and in front of, the root of the tail, from sections on a level with the electric organ, was at once evident. From the observations already made, it appears that the electric centre in the Skate closely resembles, from a morphological point of view at least, the electric centre in *Gymnotus*. The electric tract is, however, much shorter in the Skate than in the Electric Eel, and the cells are relatively fewer in number. On the other hand, the cells in the Skate are larger than in *Gymnotus*, and this is true not only of *Raia batis* but also of *R. radiata*, in which the organ is extremely small and poorly developed. Nerve-cells from the electric centres of *Torpedo*, *Gymnotus*, and *Raia* are represented in the accompanying figures. Fig. 1 represents a cell from the electric centre of the Skate (a *R. batis* two feet in length); Fig. 2 a cell from the electric centre of a well-grown *Gymnotus*; and Fig. 3 a cell from the electric lobe of a large *Torpedo*. All three figures are camera drawings, and the same lenses were used in each case—objective D and ocular 2, Zeiss. It will be noted that, though the cell from the Skate is much smaller than the *Torpedo* cell, it is decidedly larger than the one from *Gymnotus*.

In sections of the Skate's cord on a level with the electric organ, small, as well as large, cells are usually visible in the anterior horn. The small cells are in connection with the fibres which supply the untransformed caudal muscles. They agree exactly with the cells in the anterior horn throughout the entire length of the spinal cord lying in front of the electric organ region. One of these unenlarged motor cells is represented in Fig. 4. It was drawn from a section of the cord (of the same fish from which Fig. 1 was taken), about six inches in front of the electric organ. It closely resembles, except in size, the electric cell (Fig. 1), and it also resembles the large motor cells of the Mammalian cord. A motor cell from the spinal cord of a Mammal, drawn to the same scale as the other cells given, is represented in Fig. 5.[1] This cell, smaller than the electric cell of the Skate (1), and still smaller than the cell from *Torpedo* (3), is about the same size as the electric cell of *Gymnotus* (2).



With the help of sections through a series of embryo Skate, for most of which I was indebted to Dr. Beard, I have been able to study the development of the cells in the Skate's electric centre. This part of the subject, together with the condition of the electric cells in large fish, will be dealt with in a subsequent communication. It may, however, be stated now: (1) That in *R. batis* embryos under 5 cm. in length none of the motor cells in the caudal region had undergone enlargement. (2) That in an embryo 5·8 cm. in length, although the muscular fibres seemed still unchanged, certain cells in the anterior horn of the caudal portion of the cord were distinctly larger than similarly-shaped cells in their vicinity. (3) That in an embryo 15·5 cm.

[1] For the use of the section from which Fig. 5 was drawn I am indebted to Sir William Turner, F.R.S.

in length, in which the electrical elements were already well developed, the electric nerve-cells were large and conspicuous, so that sections through the cord in the region of the electric organ presented quite a different appearance from sections through the root of the tail, where no change had taken place in the cells of the anterior horn.

May 4.—"On the Differential Covariants of Plane Curves, and the Operators employed in their Development." By R. F. Gwyther, M.A., Fielden Lecturer in Mathematics, Owens College, Manchester. Communicated by Prof. Horace Lamb, F.R.S.

"On the alleged Increase of Cancer." By George King, F.I.A., F.F.A., and Arthur Newsholme, M.D., M.R.C.P. Communicated by Dr. J. S. Bristowe, F.R.S.

The general result is that the supposed increase in cancer is only apparent, and is due to improvement in diagnosis and more careful certification of the causes of death.

Chemical Society, April 20th.—Dr. Armstrong, president, in the chair. The following papers were read:—A contribution to the chemistry and physiology of foliage leaves, by H. T. Brown and G. H. Morris. This paper deals with the occurrence, relations and physiological significance of the starch, diastase and sugars contained in foliage leaves. The first part relates to the starch and diastase of leaves, and the second treats of the sugars of the leaf. A bibliography of the subject is appended. The work originated in an attempt to discover the explanation of the conditioning effect of "dry-hopping;" viz., the addition of a small amount of dry hops to finished beer. This was ultimately traced to the presence in the hop strobiles of a small, but appreciable, quantity of diastase, sufficient to cause slow hydrolysis of the non-crystallisable products of starch-transformation left in the beer, and to reduce them to a condition in which they can be fermented by the yeast. The authors were then led to enquire into the first formation of starch in the chloroplasts of the foliage leaf, the mode of its dissolution and translocation in the plant and the nature of the metabolised products; the results obtained are antagonistic to the assumption made by Sachs, that all the products of assimilation at some time take the form of starch. Only a small portion of the assimilated material exists at any one time as starch. The fluctuations in the amount of starch in leaves under various conditions were also determined. Wortmann's recent denial that diastase plays any part in the dissolution and translocation of starch in leaves is incorrect; the authors prove that, instead of leaves containing little or no diastase every leaf examined by them contained sufficient diastase to transform far more starch than the leaf can have contained at any one time. The difference between the author's and Wortmann's results is chiefly due to the faulty method of examination employed by the latter. The products of the hydrolysis of starch by leaf-diastase are identical with those formed by malt-diastase, maltose having been directly separated from the leaves; leaf-diastase is not able to convert maltose into dextrose, but the leaf contains an enzyme capable of inverting cane-sugar. The amount of diastase present varies greatly in different plants, and within narrower limits even varies in the same plant at different times; it is very high in the case of the Leguminosæ. Any conditions which favour a decrease in the leaf-starch result in an increase of the leaf-diastase; thus a marked increase in diastatic activity is observed with leaves kept in darkness. Contrary to Wortmann's statement, leaf-diastase can attack the starch-granule under certain conditions; no evidence could however be obtained of the disappearance of starch in killed leaves under the influence of the contained diastase, and the authors are led to the conclusion that the *first stage* of dissolution of the starch-granule in the leaf is in some way or other bound up with the *life* of the cell. From experiments on the leaves of *Tropæolum* the authors draw the following conclusions:—Cane-sugar is the first sugar to be synthesised by the assimilatory processes. This sugar accumulates in the cell-sap of the leaf-parenchyma whilst assimilation is proceeding vigorously, and when the concentration exceeds a certain point starch commences to be elaborated by the chloroplasts at the expense of the cane-sugar. This starch forms a more stable reserve material than the cane-sugar, and is only drawn on when the latter more readily metabolised substance has been partially used up. Cane-sugar is translocated as dextrose and levulose and the starch as maltose. From the invert-sugar derived from the cane-sugar, the dextrose is more readily used up for the respiratory processes, and possibly also for the new tissue-building, than is the levulose; hence in a given time more levulose than dextrose must pass out of the leaf into the stem. The reading of this paper was followed by an interesting discussion in which the President, Mr. Thiselton Dyer, Dr. D. H. Scott, Prof. Green and Dr. Lauder Brunton took part.—The interaction of alkali cellulose and carbon disulphide: cellulose thiocarbonates, by C. F. Cross, E. J. Bevan and C. Beadle. The maximum number of hydroxyl groups in alkali cellulose appears to be four, expressing cellulose as $C_{12}H_{20}O_{10}$. By the interaction of alkali cellulose and carbon disulphide, cellulose thiocarbonates result; these products, when treated with water, swell enormously and regenerate cellulose. From a study of a large number of these thiocarbonates the authors are led to assign to them the formula $CS\begin{cases}OX\\SNa\end{cases}$, where X is the cellulose residue, a radicle of variable dimensions. The thiocarbonates yield solutions of extraordinary viscosity.—Sulphocamphylic acid, by W. H. Perkin, jun. On heating Walters' sulphocamphylic acid, a monobasic acid, $C_9H_{14}O_2$ distils; on dissolving this in sulphuric acid sulphocamphylic acid seems to be regenerated. By oxidation with permanganate the latter yields a dibasic acid, $C_{18}H_{22}O_7$, which on reduction gives another dibasic acid, $C_{18}H_{24}O_6$. The substance of the composition $C_{18}H_{22}O_7$ yields, on hydrolysis, hydroxymetaxylenecarboxylic acid (CO_2H : Me : Me : OH = 1 : 2 : 4 : 5). A number of salts and derivatives of the above substances are described.—Magnesium diphenyl, by Lothar Meyer. In reference to a recent note by Hodgkinson (NATURE, this vol., p. 22) the author states that magnesium diphenyl has been recently prepared in his laboratory; it is a voluminous powder and is spontaneously inflammable. The formation of pyridine derivatives from unsaturated acids, by S. Ruhemann. Ethyl methyldicarboxyglutaconate yields methylmalonamide and ethyl amidoethylenedicarboxylate with aqueous ammonia; with phenylhydrazine it gives ethyl methylmalonate and the ammonium compound of the pyrazolon $PhN\begin{cases}CO.C.COOEt\\ \quad\ \ \| \\NH.CH\end{cases}$. Ethyl methylglutaconate gives β-methyl-αα'-dihydroxypyridine with aqueous ammonia and β-picoline on reduction with zinc dust. Similar reactions hold in the cases of the higher homologues of these two substances. Chlorinated phenylhydrazines, Part II., by J. T. Hewitt. Orthochlorophenylhydrazine does not yield a urazole when heated with biuret; both the meta- and para-isomerides give urazoles and their hydrochlorides yield semicarbazides with potassium cyanate. A number of other compounds are described.—The oxidation of tartaric acid in presence of iron, by H. J. H. Fenton. On adding a small quantity of hydrogen peroxide to a solution of tartaric acid containing a trace of ferrous salt, a yellow colour is produced which changes to violet on adding alkali. The substance which gives the colour with ferric salts seems to be represented by the formula $C_2H_2O_3$; it is crystalline and behaves as a powerful reducing agent. The author is still engaged in its examination.—The inertness of quicklime, by V. H. Veley. The author is still making experiments on the velocity of reaction between lime in various states of hydration and sulphurous and carbonic anhydrides at different temperatures.—The products of the interaction of tin and nitric acid, by C. H. H. Walker. This investigation is a continuation of the work of Veley on the conditions of the interactions of metals and nitric acid. The whitish substance formed by the action of fairly concentrated nitric acid on tin seems to have the composition $Sn(NO_3)(OH)_3$.—Interactions of thiourea and some haloid derivatives of fatty acids, by A. E. Dixon. Thiourea reacts with dichloracetic acid, yielding thiohydantoic acid and ultimately thiohydantoïn in accordance with the following equation:—

$$2CSN_2H_4 + CHCl_2.COOH = NH : C\begin{cases}S\text{---}CH_2\\ \qquad\ \ | \\NH.CO,\ HCl\end{cases}$$
$$+ HCl + S + H_2O + CN.NH_2.$$

α-monochlor (or brom) propionic acid interacts similarly with thiourea, giving methylthiohydantoïn; on boiling this substance with hydrochloric acid it yields β-methyldioxythiazole

$$CO\begin{cases}NH.CO\\ \qquad\ | \\S\ \text{—}CHMe\end{cases}$$

Mathematical Society, May 11.—Mr. A. B. Kempe, F.R.S., president, in the chair.—The following communications were made:—On the collapse of boiler flues, by A. E. H. Love. The problem consists in discovering the conditions of a collapse of a thin cylindrical shell under external pressure, when the ends are constrained to occupy fixed positions. Since all problems of collapse depend on the geometrical possibility of finite displacements accompanied by only infinitesimal strains, it appears at the outset that unless the shell can receive a displacement of pure bending without stretching of the middle surface collapse is impossible. The assumed condition of no terminal displacement is equivalent to closing the ends of the shell, and, since a closed surface cannot be bent without stretching, this condition apparently precludes the possibility of collapse. On the other hand it is well known that, if the external pressure exceeds a certain value, an infinitely long cylindrical shell of given small thickness and given diameter will collapse under the pressure. The critical pressure has been determined by Bryan and Basset, who find the same result. It is therefore to be expected that, if the cylinder is of sufficient length, the extensional displacement which must be superposed upon the displacement of pure bending in order to satisfy the end conditions will be practically unimportant, except in the neighbourhood of the ends. The problem is thus reduced to discovering the order of magnitude of the length of the shell in order that it may be treated as infinite when the thickness is small. For this purpose consider the case where the pressure is just equal to the critical pressure, and the displacement of pure bending in the infinite cylinder is consequently of the form

$$u = 0, \quad v = \tfrac{1}{2}A \cos 2\phi, \quad w = A \sin 2\phi,$$

where A is a small arbitrary constant. The displacement u is parallel to the generator, v is along the circular section, and w along the radius outwards. By means of displacements of this form the equations of equilibrium can be satisfied, but the boundary conditions at the ends cannot. Now take the case of an infinite cylinder with an end $x = 0$, at which v and w must vanish, and seek a displacement involving both flexure and extension of the middle surface to be superposed on the displacement given by the above form, such displacement to satisfy the equations of equilibrium and the boundary conditions:—(1) that the new v and w are equal and opposite to those above given at $x = 0$; (2) that the new u, v, w vanish at $x = \infty$. The required solution can be determined and is of the form

$$u = \epsilon^{-mx} (A_1 \cos mx + B_1 \sin mx) \sin 2\phi,$$
$$v = \epsilon^{-mx} (A_2 \cos mx + B_2 \sin mx) \cos 2\phi,$$
$$w = \epsilon^{-mx} \frac{m^2 d^2}{4(2 + \sigma)} (B_2 \cos mx - A_2 \sin mx) \sin 2\phi,$$

in which B_2 and A_2 can be determined so as to satisfy the conditions at $x = 0$, σ is the Poisson's ratio of the material of the shell, and

$$m = [12(1 - \sigma^2)]^{\frac{1}{4}} / \sqrt{(dt)},$$

t is the thickness and d the diameter of the shell. If σ be taken equal to $\frac{1}{4}$ the reciprocal of m is about ·546 of the mean proportional between the thickness and the diameter, and it follows that whenever x is great compared with this quantity the influence of the end is unimportant, and the displacement approximates to one of pure bending. To make the tendency to collapse occur in practice, it would be necessary that the half length of the flue be great compared with m^{-1}, and the practical conclusion would be that for a flue of length l stability would be secured if

$$\tfrac{1}{2}l < n/m, \text{ or } l < N \sqrt{(dt)},$$

where N is a considerable number. It is customary in stationary boilers to make the flues in detached pieces connected by massive flanged joints, so that the effective length of the flue is the distance between consecutive joints. If the number N be taken equal to 12 we have the rule that the distance between the joints must be not greater than twelve times the mean proportional between the thickness and the diameter. The value $N = 12$ accords well with what has been found safe in practice, but the rule as to spacing the joints is new.—On some formulæ of Codazzi and Weingarten in relation to the application of surfaces to each other, by Prof. Cayley, F.R.S.—On the expansion of some infinite products, by Prof. L. J. Rogers.—On a theorem for bicircular quartics and for cyclides corresponding to Ivory's theorem for conics and conicoids, by Mr. A. L. Dixon. Using a form of the equation to these curves and surfaces (in quadricircular and pentaspherical co-ordinates) already studied by Darboux and Casey, the writer deduced that the ratio of the distance of any two points to the product of the lengths of the tangents from them to a fixed focal circle or sphere is the same as for the pair of corresponding points. He also showed how the theorem for the Cartesian oval could be derived from its equation in terms of elliptic functions.—A supplementary note on complex primes formed with the fifth roots of unity, by Prof. Lloyd Tanner. The author investigates a method of determining whether a complex number is prime or composite. The process takes two distinct forms, one of which was established, on different grounds, by Tchébicheff. The other appears to be new, and is convenient in testing the sets of complex integers described in the author's previous communication on the subject. The discussion is based upon a certain classification of complex integers according to the "orders" of their complexity, and this conception facilitates the direct factorization of complex numbers. The theory is restricted to the case of 5, but seems to be quite general.—On the linear transformations between two quadrics, by Mr. H. Faber. In *Crelle's Journal*, vol. v. (also Phil. Trans., 1858), Cayley gave a representation of the automorphic linear transformation of the unipartite quadric function in the notation of the theory of matrices. In the present paper the author extends Cayley's method to the determination of the general linear transformation of a given quadric into another given quadric, and applies the results to the determination of the general real linear transformation between two equivalent quadrics and to the reduction of a quadric to a sum of squares. The determination by this method of the general linear transformation between two quadrics depends upon the solution of an algebraic equation of the n^{th} degree, to which the problem as it originally presents itself—viz., the solution of a system of n^2 quadratic equations in n^2 variables, is thus reducible.—On maps and the problem of four colours, by Prince C. de Polignac.—On Fermat's proof of the problem that primes of the form $4n + 1$ can be expressed as the sum of two squares, by Mr. S. Roberts, F.R.S.

Entomological Society, May 10, Mr. Henry John Elwes, President in the chair.—Mr. R. McLachlan, F.R.S., exhibited for Dr. Fritz-Müller, of Blumenau, Santa Catarina, Brazil, specimens of larvæ and pupæ of a dipterous insect, and read a letter from Dr. Fritz-Müller on the subject. The writer stated that the larvæ were similar to those exhibited by Mr. Gahan, at a meeting of the society in October, 1890, and which were then thought by Lord Walsingham, F.R.S., and Mr. McLachlan, to be allied to the Myriapoda.—Mr. S. G. C. Russell exhibited specimens of *Hesperia alveolus*, including one of the variety *Taras*, taken by him at Woking in April last.—Mr. J. M. Adye exhibited a long series of *Moma orion*, *Eurymene dolobraria*, *Amphidasis betularia*, *Cloephora prasinana*, and a few specimens of *Notodonta dodonea*, *N. chaonia*, and *N. trepida*, *Acronycta alni*, and *Selenia illustraria*, all bred by him in March and April last, from larvæ obtained in the autumn of 1892 in the New Forest.—Mr. H. Goss read a copy of a letter received by the Marquis of Ripon, at the Colonial Office, from the Governor of the Gold Coast, reporting the occurrence of vast swarms of locusts at Aburi and Accra, West Africa, about the middle of February last. The writer stated that at Accra the swarm extended from east to west as far as the eye could see, and appeared to occupy a space about two miles wide and from a quarter of a mile to a mile in height.—Colonel Swinhoe stated that some years ago he had been requested by the Indian Government to report on plagues of locusts. He said he had witnessed swarms of these insects far larger than the one just reported from the Gold Coast, and mentioned that many years ago, when going up the Red Sea in one of the old P. and O. paddle boats, the boat had frequently to stop to clear her paddle-wheels from locusts, which had settled in such swarms as to choke the wheels and stop their action.—Mr. E. C. Reed, of Valparaiso, Chili, communicated a paper entitled "Notes on *Acridium paranense*, the migratory locust of the Argentine Republic." Colonel Swinhoe, Mr. Champion, Mr. Elwes, Mr. McLachlan, and Mr. Merrifield took part in the discussion which ensued.—Prof. L. C. Miall, F.R.S., communicated a paper entitled "Dicranota; a Carnivorous Tipulid Larva."—Dr. T. A. Chapman communicated a paper entitled "On a Lepidopterous pupa (*Micropteryx purpurella*) with functionally active mandibles." Mr. McLachlan said he thought Dr. Chapman's observations were of great value, and tended to show that the position of *Micropteryx* was nearer the Trichoptera than had been supposed.—The President announced that the new Library Catalogue, which had been edited by Mr. Champion, with the assistance of Mr. McLachlan and Dr. Sharp, F.R.S., was now ready.

PARIS.

Academy of Sciences, May 15.—M. Lœwy in the chair.—On the quantitative determination of boron, by M. Henri Moissan. The determination is based upon Gooch's methyl alcohol method, in which several improvements were introduced. The boron is first obtained in the state of boracic acid by treating with nitric acid in a sealed tube. The boracic acid is separated by means of pure methyl alcohol. The reaction takes place in a bulb tube provided with a funnel which reaches down into the bulb and can be closed by a cock. Four distillations with alcohol are carried out, the vapours passing through a coil of glass tubing into a Bohemian glass flask. Any uncondensed vapour is absorbed by ammonia solution. The liquid collected is poured upon a known weight of pure slaked lime, forming calcium borate. The latter is calcined and weighed, and the increase of weight gives the amount of boric anhydride absorbed. To test whether the boron has all distilled over, a drop of the distilling liquid is caught on a strip of paper and placed in a flame, when a green colour will indicate any trace of boron. The slaked lime is kept, when not in use, in the form of a stable basic nitrate, which is made ready for use by a strong calcination. The quantity of lime should be 16 to 20 times the probable quantity of boracic acid. The process, though still somewhat laborious, has given very consistent results.—The working of the soil and nitrification, by M. P. P. Déhérain.—Re-appearance of certain latent affections (etiology and pathogeny), by M. P. Verneuil.—Results obtained with mixtures of butters and diverse fatty materials by means of the new method for the recognition of adulteration of butter, by M. Auguste Houzeau.—On the terms of the second order resulting from the combination of aberration and refraction, by M. Folie.—On the observation of the total eclipse of the sun of 16th April, made at Fundium (Senegal), by M. H. Deslandres.—The solar eclipse of 16th April, 1893, at the Vatican observatory, by P. F. Denza.—On a class of systems of ordinary differential equations, by M. Vessiot.—On the generalisation of the analytical functions, by M. G. Scheffers.—On the cases of integrability of the motion of a point in a plane, by M. Elliott.—On the general law and the formulæ of the flow of saturated water vapour, by M. H. Parenty.—On the dimensions of absolute temperature, by M. H. Abraham.—On a new kind of manometer, by M. Villard.—On the inversion of Peltier's phenomenon between two electrolytes beyond the neutral point, by M. Henri Bagard.—Study of the cadmium and sal-ammoniæ cell, by M. A. Ditte.—Influence of the temperature of tempering upon the mechanical properties and the structure of brass, by M. G. Charpy.—On malic acid substitutions, by M. Ph. A. Guye.—Action of chloride of zinc upon chlorocamphor, by M. A. Etard.—On a certain number of organo-metallic combinations belonging to the aromatic series, by M. G. Perrier.—Inulasis and indirect alcoholic fermentation of inuline, by M. Em. Bourquelot.—Chemical phenomena of assimilation of carbonic acid by chlorophyll-bearing plants, by M. A. Bach.—On the meteoric iron of Augustinowka (Russia), by M. Stanislas Meunier.—Influence of the medium on respiration in the frog, by M. A. Dissard.—Action of oxygen and compressed air upon warm-blooded animals, by M. G. Phillippon.—On the ophthalmic nerves of *Spondylus Gœderopus*, by M. Joannes Chatin.—On the parthogenetic fragmentation of the ovules of mammifers during atresia of the Graafian follicles, by M. L. F. Henneguy.

AMSTERDAM.

Royal Academy of Sciences, April 28.—Prof. van de Sande Bakhuyzen in the chair.—Mr. Kamerlingh Onnes exhibited isogonic charts for 1540, 1580, 1610, 1640, 1665, and 1680, drawn by Dr. van Bemmelen according to observations discovered by him in old, especially Dutch books, in the manuscripts of van Swinden and in old Dutch ship-journals.—Mr. Franchimont treated of hydrocyanic acid in plants. A short time ago Mr. van Romburgh found hydrocyanic acid, probably as an unstable compound with acetone (and perhaps with glycose), in the caoutchouc-yielding plants *Manihot glaziovii*, Müll. Arg., *Hevea brasiliensis*, Müll. Arg., and *Hevea spruceana*. Now Mr. van Romburgh has examined Indigofera's, and found that the leaves of the *Indigofera galegoides* D.C. (*Tarvem octan*), which do not produce indigo, and have no particular smell, yield a considerable quantity of hydrocyanic acid and of benzaldehyde by being weakened in water for two hours. By new researches Mr. van Romburgh will try to find out if this Indigofera contains amygdaline or laurocerasine, and whether the enzyme, to which the decomposition is due, is identical or not with emulsine. This seems to be the first time that hydrocyanic acid has been found in a plant belonging to the family of the Papilionaceæ.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Catalogue of the Library of the Entomological Society of London, edited by G. C. Champion (London).—Evolution and Religion: A. J. Dadson (Sonnenschein).—Zoology of the Invertebrata: A. E. Shipley (Black).—Archæological Survey of Egypt; Beni Hasan. Part 1: P. E. Newberry (K. Paul).—Some Further Recollections of a Happy Life (Macmillan).—Helps to the Study of the Bible (Oxford University Press).—A History of Crustacea: Rev. T. R. R. Stebbing (K. Paul).

PAMPHLETS.—Manchester Museum, Owens College Museum Handbooks, Outline Classification of the Animal Kingdom, 2nd edition (Manchester, Cornish).—Outline Classification of the Vegetable Kingdom (Manchester, Cornish).—Catalogue of the Type Fossils: H. Bolton (Manchester, Cornish).—The Romanes Lecture. 1893—Evolution and Ethics: T. H. Huxley (Macmillan).—Syllabus of Elementary Course of Botany: J. B. Philip (Aberdeen, Bisset).

SERIALS.—Dictionary of Political Economy, Part 5 (Macmillan).—Astronomy and Astro-Physics, May (Northfield).—Journal of the College of Science, Imperial University, Japan, vol. 6, Part 1 (Tōkyō).—American Journal of Mathematics, vol. xv. No. 2 (Baltimore).—Botanische Jahrbücher für Systematik, Pflanzengeschichte und Pflanzengeographie, Siebzehnter Band. 1.u. 2 Heft (Williams and Norgate).

THURSDAY, JUNE 1, 1893.

MODERN METEOROLOGY

Modern Meteorology: an Outline of the Growth and Present Condition of Some of its Phases. By Frank Waldo, Ph.D., Member of the German and Austrian Meteorological Societies, late Junior Professor, Signal Service, U.S.A. (London: Walter Scott, 1893.)

IF it be true that the condition of the weather forms a general and engrossing topic for conversation among Englishmen, books which treat of meteorology should attract the attention of many readers in this country, and Dr. Waldo be assured of many students. But in this particular work the author has not dwelt upon the more popular side of the subject, he has not exhibited the capacity for making weather forecasts, or discussed the success which has attended such predictions, or the future that lies before work of that description. He has had in view rather that smaller class of readers, with whom meteorology means something real and hopeful, and who by accurate and patient work are earnestly striving to make it rank among the exact sciences. Considering the very substantial progress that meteorology has made, the opinion is shared by many, possibly by the author of this work, that the day has already come when this science is entitled to rank among the older and more systematised branches of scientific inquiry. This is entirely to misconceive the situation. Just as incorrect and unfair would it be, to see in the widely scattered and ardent meteorological observers, a class, whose power and knowledge are limited to the acquisition of the readings of barometers and thermometers, Meteorology may not yet have produced its Kepler. certainly not its Newton, but working hypotheses, founded on rigorous dynamical principles are everywhere being tested, amended, harmonised with observed facts, showing that the days of simple accumulation of observations are giving place to a new and more hopeful era. It is with the earnest hope of encouraging and instructing this army of observers, that Dr. Waldo in this little book endeavours to place before them the most recent results, which the pioneers of meteorology are seeking to establish with a fair prospect of success.

Dr. Waldo explains that he is mainly a student of what may be termed the German school of meteorology, a fact which may be expected to colour his work very materially. Practically it has its advantages and disadvantages. The views supported by that school are set forth at very considerable length, and since the ordinary English reader may not have had the same opportunities for making himself acquainted with the original memoirs that Dr. Waldo has enjoyed, it is a great advantage to be introduced to the special teaching of von Bezold, or of Oberbeck, or von Helmholtz, by one who has graduated in that school with no mean honours. On the other hand it is curious to the English reader, to find names which are as familiar to him as household words, authorities which he is accustomed to hold in the highest respect, passed over with the briefest mention and apparently as undeserving of consideration. This is a disadvantage both to the author and reader. The author admits the drawback and apologises for omissions to French and English authorities, while in the student it is liable to produce a sense of disproportion and exaggeration, and even of unfairness to his own countrymen. But with this exception, understood and allowed for, this book is a valuable contribution to the literature of the subject.

In an introductory chapter, which might have been extended with advantage, the author gives a rapid but admirable sketch of the various sources whence the recent history of meteorology may be gathered. These sources include not only distinct treatises and the periodical literature, but the work accomplished and recorded at the various congresses that have been held from time to time. This latter portion is treated in a very sketchy manner, and might have been much enlarged, lest the importance of such gatherings and the international benefits to be derived therefrom should be overlooked.

The second chapter, which is practically a book of nearly two hundred pages, will certainly not be considered the least satisfactory part of the volume. Here is given the history and description of the more important of the meteorological instruments, with their methods of use, and given too, at great length, because the author asserts that there is no work in English which gives an adequate description of such instruments. Without endorsing this somewhat sweeping assertion, there can be no doubt but that this chapter is eminently worthy the attention of those for whom in a great measure the book is intended—the teachers of physical geography and elementary physics. The author is as a rule fortunate both in what he inserts and in what he omits in his descriptions. His remarks on normal barometers are especially valuable and will be much appreciated. Dr. Waldo is particularly qualified to speak on questions touching the construction of these instruments, for we believe he was engaged in comparing the accuracy of the various standard barometers in use in the principal observatories in Europe.

In the section on wind-measuring apparatus, is well illustrated that feature to which attention has been called, the small regard paid to English experiments in meteorological inquiries. We place very considerable confidence, in this country at least, in the researches of Mr. Dines, and are disposed to consider him as an authority on the proper constant to be employed in the reduction of the indications of Robinson's anemometer. It is true these researches are not altogether ignored, but they are dismissed in a couple of lines, which though they may give fairly accurately one of the principal results of his work do not in any adequate degree express the value of his inquiry, and this omission, if such it can be called, contrasts very remarkably with the enormous space which is given a little further on to the description of the instruments and the record of the hourly and momentary occupation of the staff at the Pawlowsk observatory. We have no wish to disparage this, possibly, first of meteorological observatories. We believe all that experience can suggest and devotion effect to secure accuracy and well directed observation is done here. It may well be that Pawlowsk presents us with an ideal meteorological observatory, supported with magnificence and directed with equal energy and ability. But the scale of magnificence depicted is more likely to breed a spirit of discontent in those who do excellent work with smaller means, than furnish a scheme on which they can conduct their more modest establishments. We are the more disposed to quarrel with the author for the space devoted to this long and tedious description because we feel that useful matter which Dr. Waldo could so ably have contributed has been crowded out. Under the title "Apparatus and Methods" we could have hoped space would have been found for "Methods of Reduction." Dr. Waldo admits not only that the ordinary observer is at times at a loss for reliable guidance in the reduction and discussion of a particular series of observation, but that the specialist in other inquiries into which meteorology enters or may enter cannot find the observations put into a form ready for use. Possibly the author feels that the subject of reduction is sufficiently large to demand a treatise to itself, but nevertheless many a meteorologist who has carefully tabulated his readings, for years it may be, would turn to a book expressly addressed to himself in the hope of finding some hints, which would enable him to extract something useful from his observations or at least to reduce them on systematic and uniform lines.

Having dismissed the subject of instruments and observatories, the author proceeds to discuss the Thermodynamics and general motions of the atmosphere, and these two chapters, upon which has evidently been lavished an immense amount of care, sustain the interest of the book and carry us a long way into a very difficult subject. It cannot be said that these chapters are light reading. The author has attempted a difficult, it may be an impossible task, for he virtually proposes to give the results of mathematical analysis without the use of mathematical symbols. Such forms of descriptive writing are seldom a success for any class of readers and it is scarcely too much to say that any one who can follow the successive steps of the argument, put forward by the various authorities here quoted, would find his work easier if the author had not dispensed with the assistance of ordinary symbols. But any one who struggles successfully with the difficulties of these chapters will find himself put in possession of the latest views of the exponents, of what the author has called the German School of Meteorology, though at the head of it we should place Prof. Ferrel with his high American reputation.

Of the views of the various authorities here set out, we think Prof. Ferrel fares the best, as being most clearly expressed and in the completest detail, but in this instance Dr. Waldo was assisted by the fact that Prof. Ferrel has himself translated his book on "Recent Advances in Meteorology," published under the auspices of the United States Government in 1885, into a popular treatise on "The Winds." We are thus enabled to have in this section and particularly in the following one on the "Secondary Motions of the Atmosphere," copious extracts from Prof. Ferrel's book in his own words, and this is extremely fortunate, for Ferrel's views have altered not a little since he first submitted them to public consideration, and it is a little difficult to be certain that we have the last words of this distinguished meteorologist. For the remainder, it would be a great advantage to the reader if the various views quoted from the original authorities were not left so disconnected, but the points of harmony and divergence brought into stronger relief. The author is too content to stand in the background and allow the various authorities to put forward their views without sufficiently accentuating their strong points. Indeed, it would seem at times as though the several points of divergence were not fully appreciated. We may illustrate this peculiarity by an instance which also shows the indifference of the author to English authorities on the theoretical side, a peculiarity to which we have already called attention in practical work. In the historical account of Ferrel's work is mentioned (p. 275) the fact that Prof. James Thomson published a paper in the Proceedings of the British Association, 1857, "expressing somewhat of the same dissatisfaction with current theories that Ferrel had printed in 1856, and the line of reasoning as regards a new theory was much of the same nature, but not so complete as Ferrel's. This paper is now chiefly valuable historically." Then follows a defence of the late Prof. Thomson against a possible charge of plagiarism. We doubt whether this defence will be appreciated, for in 1857 the views of the Glasgow Professor differed widely from those held by Prof. Ferrel. That they have gradually approached since, is due rather to the fact that Ferrel has modified his views as originally held. The distinguishing feature, or at least one distinguishing feature, in the theory of the latter, a theory which Prof Thomson had characterised as pervaded by impossibilities and incongruities, is the assertion that there must be a heaping up of the top layers of the atmosphere to a maximum height at about the parallel of 28°, and a depression of them not only over the Equator but around the Poles and in high latitudes generally. He would thus produce six zonal vortex rings of circulation, three in the Northern and three in the Southern Hemisphere. Prof. Thomson's theory was a modification of the older theory of Hadley, recognising and emphasising the conditions to which a thin stratum of air would be submitted under the effects of friction and impingement at the earth's surface. As the final outcome of his theory, Prof. Thomson concluded that in temperate latitudes, there are three currents at different heights :—"That the uppermost moves towards the Pole and is part of a grand primary circulation between equatorial and polar regions; that the lowermost moves towards the Pole, but is only a thin stratum forming part of a secondary circulation; that the middle current moves from the Pole and constitutes the return current for both the preceding, and that all these three currents have a prevailing motion from west to east in advance of the earth."[1] Those who have followed the development of Prof. Ferrel's ideas will find and will admit, that his later theory, published in 1860 bears a far greater likeness to that published by Prof. Thomson in 1857, than it does to his own earlier efforts in 1856. If there be any plagiarism, and it is not at all necessary that there should be, since the change of view could be amply explained by the gradual growth and improvement of Ferrel's views in the interval, it can scarcely affect the reputation of the English meteorologist.

But the value of the book is not to be measured by

[1] Phil. Trans. vol. 1893 A. p. 675.

the appreciation the author may have of English work. That it would have been better written if his reading had been wider or his acquaintance with the English literature of the subject more thorough, Dr. Waldo would himself admit. The object of the book is distinctly to make known in English reading circles what has been effected on the Continent by the studies of Von Bezold, Siemens and others, and this object is well executed. The exhibition of the views of these masters in lucid terms, and with a few exceptions the author makes his meaning very clear, is more than a sufficient reason for the appearance of the book, which will be welcomed by many students, who are thus put in easy possession of much abstruse work, which possibly embodies the more or less crudely shaped views that they themselves have held, but have been unable adequately to express.

WILLIAM E. PLUMMER.

THE TRANSMISSION OF TELEPHONE CURRENTS.

Telephone Lines and their Properties. By William J. Hopkins. (London: Longmans, Green and Co.)

IN this book the author has attempted the difficult task of instructing both the student and the practical man, and the result is, on the whole, more successful than is usually the case. The first half of the book is a text-book of the modern practice of telephone lines in America, and contains a large amount of good and interesting information on overhead and underground lines, poles, insulators, wires, conduits, cables, exchanges, and switchboards. This covers too wide a field to be useful to a telephone engineer, as each subject is necessarily treated in a cursory manner, but to an English reader it is very interesting, if he knows enough of his own practice to note and appreciate the points of difference. Some of these indeed will make the general public thankful for the restrictions under which telephone men labour over here, and one of the illustrations—a street telephone pole, about 100 feet high, with eighteen heavy wooden cross-arms—is a testimonial to the patience of American people. One or two of the explanations of facts outside strictly electrical information require revision; for instance, the coating formed on copper wire exposed to damp air is the hydrated carbonate of copper, and not the chloride, as stated by the author. Also the dictum on cables for underground circuits is somewhat curious, indiarubber insulation being condemned as not impervious to moisture, and liable to soften by heating, thereby allowing the wire to sink through the insulation. Considering that in another part of the book a current of ten milliamperes is given as a maximum for telephone work, it is difficult to see how any appreciable heating is to take place, as the current density is such as would rejoice the heart of Mr. Heaphy. Again, the accusation that indiarubber will not exclude moisture for a longer time than anything else, makes one wonder what they make it of in America. But after all these may be differences of opinion, and in general the information is unusually accurate. and is very clearly expressed. The only exception to this is in the chapter on switchboards, where the frequent use of technical terms is likely to give some difficulty to a student who is ignorant of practice. The addition of inverted commas to a technical expression is small assistance, where no explanation of its meaning is volunteered.

The second half of the book rises above the text-book standard, and gives a very good account of recent work on the bearing of the capacity and inductance of a circuit on its transmitting power, and the effect of the configuration of itself and neighbouring wires, on its freedom from cross-talk and external influences. The paper of Mr. J. J. Carty, of New York, on the effects of electrostatic induction from neighbouring wires is largely quoted from and discussed, and his theory of the phenomena energetically advocated. A large number of experiments are described in a very clear manner, and the deductions seem mostly incontestable. But the law connecting length of wires that run parallel with each other with the amount of cross-talk produced seems incorrect. It is founded on only one series of experiments, and is given as $C=k\sqrt{l}$ where C is the induced current and l is the length of parallel line. It should surely be of the form $C=kl/(R+r)$ where R and r are the impedance of the receiving instruments, and of the whole length of line respectively.

The experiments very ingeniously show that by electrostatic induction the charged wire will induce a charge in the neighbouring wires, and a series of such induced charges in opposite directions make an alternating current similar to the primary current. The comparatively high potential of a telephone wire and the extremely small current render this explanation the only possible one, and the absence of electro-magnetic induction even from a much larger current is shown by simple experiments. After this the method of shielding the line by symmetrical arrangement, or by stranding or transposition of the wires is clearly explained, as the induced current causing cross-talk is reversed in direction at every turn, so that only the last section will affect the receiving instruments. After considering air lines, the author gives a careful investigation of the construction of cables, with the effects of large capacity and the methods of reducing it. Cross-talk is also considered, and designs for non-inductive cables suggested. The unequal efficiency of composite lines from the two ends is mentioned with unnecessary hesitation as to the reality of the fact, and no definite explanation is offered. It is found best to have the larger capacity at the sending end, probably because there is a considerable loss of electricity in transmission, and hence a smaller current over the larger half of the line, whereas in the reverse direction a large current has to be transmitted over a great distance, only to be, to a great extent, absorbed in the capacious cable.

The chapter on external influences is written with impartiality and completeness, and contains an account of some curious observations on the effect of tramways and electric lighting wires. Some good advice is given on the methods of avoiding disturbance, the double metallic circuit being recognized as the only completely satisfactory way out of the difficulty. An account of one instance of disturbance is sufficiently alarming, that a small arc lamp was maintained in a telephone circuit during a magnetic storm! If this source were only more regular, it might be another solution of what to do when the coal gives out. An elaborate investigation of the action of electric light circuits ends in a set of rules and restrictions for the electric light engineer so stringent and complicated that it would effectually check all disturbances by frightening off a contractor altogether, and a three-wire system would be rendered impossible. However the author recognises that the best remedy lies in the telephone engineer's own hands.

The book concludes with a reprint of a paper by Mr. J. J. Carthy on Inductive Disturbances in Telephone Circuits.

The general style of the book is good and intelligible, and the diagrams clear and new, the old familiar text-book pictures being rigidly excluded. The arrangement into chapters and headings is carefully done, though in the endeavour to make each one complete some repetition is unavoidable. The reason of the omission of an index at the end is hard to understand, as its use in a book intended to be kept is undoubted, and the insertion of the title of the book on every page instead of that of the chapter does not mend matters. As the author states, the mathematical processes have been mostly omitted, or inserted as footnotes. But the few that are found in the latter place might just as well have been left out. For instance, to quote Lord Kelvin's somewhat complicated formula for the current density at any point in a conductor is not so useful as a reference to his original paper would have been, and the formula is not used to obtain any result. Immediately after this follows a remarkable *proof* that $dN/dt = E$. The use of the term "volume" for "current" is needlessly unscientific, but in general the terminology is accurate and consistent. That comprehensive but dangerous word, "retardation" is used with careful explanation of the component parts of its cause, though in one or two places it is loosely employed for "inductance," or "capacity," with consequent inaccuracy.

To sum up, it will be found a useful and very readable book, giving information not otherwise easily obtainable, and both practical men and students will find it repay careful reading.

FRANCIS G. BAILY.

MODERN PURE GEOMETRY.

An Elementary Treatise on Modern Pure Geometry. By R. Lachlan, M.A. (Macmillan, 1893.)

BY a recent regulation for the Cambridge Mathematical Tripos provision is made for the introduction of a paper on "Pure Geometry": this to include, in addition to Euclid, the simple properties of lines and circles, the elementary properties of conic sections treated geometrically, for which a place has already been found, such questions as may be treated by inversion, reciprocation, and by harmonics. It has been for some time a reproach that pure geometry has not occupied a more prominent position in the University curriculum. The University has never lacked able geometers, and amongst the present generation our author has won for himself a good name. He has put together an excellent manual complete enough to meet present wants, and doubtless in subsequent editions he will bring the present work even more up to date than it is. Some of our best text-books are overloaded with corollaries and much other matter which it is difficult for the student to retain clearly in his mind. Mr. Lachlan appears to us to have steered a most judicious course, and avoided overloading his book in this way. Mr. Pinto (in "Lothair") speaking of the limited range of the English language (which, however, he admitted to be expressive), said it consists of four words. If this be so, the word we should select to characterise Mr. Lachlan's essay is that it is "charming." It treats of the subject in sixteen chapters, in which, after devoting the first three to an introduction, measurement of geometrical magnitudes and fundamental metrical propositions, he starts from harmonic ranges and pencils, and carries the student at once to the theory of involution. He then discusses properties of the triangle (giving an account here of the recent additions to this branch of the subject, from which we infer that it has at length got a footing in the University) and of rectilinear figures. The reader then has laid before him a clear account of the theories of perspective, of similar figures (previously introduced to English readers in Casey's "Sequel"), and of reciprocation. The properties of the circle are discussed under the heads of the circle as a figure by itself, and then in relation to one or more circles. In this division of the subject our author gives account of his own discoveries and of the many interesting additions contributed by Mr A. Larmor. In two remaining chapters the theories of inversion and of cross ratio are unfolded. The treatment in the text is strictly confined to the line and circle. We believe that a further volume extending the methods herein employed to the conic sections is in course of preparation. A few slips have caught our eye, viz. p. 53, ex. 4; § 97 ex.; p. 55, ex. 7; § 116; § 262; § 268, and one or two other easily corrected mistakes. In such a mass of mathematical work there may well be others. References are given to the sources whence many of the questions are taken. We note that an oversight, which we have had occasion to point out twice before in NATURE in reviewing the late Dr. Casey's "Sequel," is perpetuated here. On pp. 68, 71, a question is cited from a "Trin. Coll., 1889" paper, whereas it was given many years previously in the *Educational Times* (Feb., 1865, and April), and was then by a correspondent carried back to Steiner (Crelle, vol. liii.). Th e figures illustrate the text very clearly, and there is a full index at the end.

OUR BOOK SHELF.

An Analytical Index to the Works of the late John Gould, F.R.S. By R. Bowdler Sharpe, LL.D. With a Biographical Memoir and Portrait. (London: Henry Sotheran and Co., 1893).

THE compiler of the present work mentions in the preface that the need for it was originally suggested in the course of a discussion between Lord Wharncliffe and Lord Walsingham as to some ornithological question. They decided to refer to one of Gould's plates, but could not readily find the volume in which the figure was given. It occurred to both of them that "such a difficulty would not arise if there existed a complete 'Index' to all the folio works issued by Gould," and Lord Wharncliffe asked Mr. Bowdler Sharpe whether he would undertake the preparation of the kind of volume that was wanted. As Messrs. Sotheran were willing to publish an "Index," Mr. Sharpe set about the task, hoping to be able to accomplish it within a reasonably short period. As a matter of fact, he says, the enterprise "has taken me as many years to finish as I expected it would have taken months." The "Index" does not relate to all the papers published by Gould in various journals, but it does include every work which he issued separately, whether in folio, or octavo, or quarto form; and Mr. Sharpe, with the aid of his assistant at the Natural History Museum, has been careful to check the various references, the number of which is nearly seventeen thousand. He has also put in some "extra synonyms from popular works, such, for instance, as Oates's 'Birds of British India,' which in a few years will have familiarised Indian naturalists and sportsmen with a certain set of names which do not occur in Gould's works, though the species may be duly figured therein." The work, which is very handsomely "got up," will be of great value to all who are fortunate enough to possess Gould's writings, and it will frequently be of good service to every serious student of ornithology. In the biographical memoir Mr. Sharpe not only presents the leading facts of Gould's career, but has much that is fresh and interesting to say about the results of his scientific labours and about the essential qualities of his character.

An Elementary Treatise on Pure Geometry, with numerous examples. By J. W. Russell. (Oxford: Clarendon Press, 1893.)

THE opening sentence of the Preface—"The author has attempted to bring together all the well-known theorems and examples connected with Harmonics, Anharmonics, Involution, Projection (including Homology), and Reciprocation"—indicates that the writer has given himself a "tall order." Within the limits of 323 pages we have here collected every possible property that a student can desire to have. Our only objection to the book is that it is too full for ordinary purposes, but as the matter is put together with considerable skill and ability—thus evidencing the writer's familiarity with, and mastery over, his subject—and illustrated with a choice collection of worked-out exercises, we cordially commend it. We could wish that a handbook for school use were founded upon it. There used to be a rumour abroad that the late Prof. Henry Smith intended to publish his Geometrical Lectures. That hope is now, we presume, frustrated, but as Mr. Russell's first lessons in Pure Geometry were learnt from Mr. Smith's lectures, and as many of the proofs of the present work are derived from the same source, we must possibly take it as the substitute for the "Geometrical Lectures." The get-up of the text is on the usual lines of the Clarendon Press and is all that one could desire.

Sun, Moon, and Stars: Astronomy for Beginners. By A. Gilberne. (Seeley and Co., Limited).

THIS small book comprises 300 pages of matter, and contains a most interesting account of the various members of the solar system and other celestial objects more remote. The narrative is particularly adapted to a large class of people who desire to know somewhat of the wonders and awe-inspiring phenomena connected with the science of astronomy without making a special study of them; yet sufficient interest is aroused to induce a beginner to search for more information. The work, however, does not claim to be a text book, although to a beginner it will serve as a capital starting-point. It is printed in open and pleasing type, and contains instructive illustrations. A few passages might be somewhat improved upon, as for example, p. 143—

"It is said that a cannon-ball, reposing on the sun, if lifted one inch and allowed to fall, would dash against the ground with a speed three times greater than that of our fastest express-trains."

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Mr. H. O. Forbes's Discoveries in the Chatham Islands.

UNWILLING as I am to interpose in the discussion between Mr. Wallace and Mr. Forbes (*supra* pp. 27, 74), yet each of those gentlemen having referred to opinions formerly expressed by my brother and myself, it seems fitting that I should offer a few words on the present occasion, if it were only to avoid misapprehension; but I would premise that I have not seen Mr. Forbes's paper read before the Geographical Society or his article in the *Fortnightly Review*. To this I would add that I am no more ashamed of opinions in the utterance of which before the Royal Society in 1868 I took a share, than I am of having then been a quarter of a century younger than I am now. Whether they are to be considered modified by what I published some halfdozen years later, when I next touched upon the subject, I do not greatly care, and leave to the judgment of those (if any there be) who may take the trouble of comparing the passage in the *Philosophical Transactions* (1869, pp. 357, 358) with that in the "Encyclopædia Britannica" (ed. 9, iii. p. 760); and what I now think, or at least thought some eighteen months ago, when the last thing I wrote on the question was passed for press, will I hope be before the public in October.

However I would point out that one thing seems needed to make this discussion real, and that is proof of the assertion, made in NATURE—at first tentatively (xlv. p. 416), then positively (*tom. sit.*, p. 580), and again with fuller details (xlvi. p. 252), that *Aphanapteryx* ever inhabited the Chatham Islands. Mr. Forbes has been so kind as to show me on two occasions the bones which he ascribed to a species of that genus, and I was fortunately able to let him compare them with those of the real *Aphanapteryx* in the Museum of this University, being all that have as yet been recovered from Mauritius. I pointed out to him differences between the remains of the two forms which appeared to me of generic value, and I thought I had satisfied him on this score, since he did me the honour of asking me to suggest a new name for the form which he had discovered. In that view I was confirmed by finding that, shortly after his last visit to Cambridge, he described the Chatham-Islands bird as *Diaphorapteryx* at a meeting of the British Ornithologists' Club on 21 December, 1892, as I learn from its printed *Bulletin* (No. IV. p. xxi.). All this would matter little to any but specialists did it not seem that what Mr. Wallace rightly terms a "tremendous hypothesis" is based on the asserted existence of *Aphanapteryx* in the Chatham Islands, and I understand that, on the strength of the assertion, further daring speculations have been indulged in, to support which Purple Waterhens, extinct or expiring Starlings, and what beside I know not, have been dragged in. Whether the additional evidence is worth anything remains to be seen; but though I fully recognise the importance of Mr. Forbes's discoveries, rightly interpreted, we are as yet without proof that *Aphanapteryx* inhabited any part of the New Zealand Region; and if it did not, then as regards the speculations based upon it *cadit quæstio*.

ALFRED NEWTON.

Magdalene College, Cambridge, 27 May.

The Fundamental Axioms of Dynamics.

REFERRING to my previous article in NATURE on the above subject (May 18, vol. xlviii. p. 62), there are a few explanatory remarks which may be usefully made,—most of them suggested by the recent discussion at the Physical Society, especially as summarised by the President (Prof. Rücker).

There seems to be some feeling against the advisability of ascending successive steps in a ladder of reasoning unless there be already some perception as to what is to be met with on the top. If the ladder shows signs of ending in a medium of unknown and in some respects paradoxical properties, that fact appears to be felt as an inducement to mistrust the steps which lead thither.

But it must surely be admitted that if each rung is in itself firm and strong, and if successive rungs follow one another with a reasonable amount of sequence, then we ought fearlessly to mount and abandon ourselves whithersoever they lead, quite irrespective of dim suspicions about unacceptable consequences.

Some doubt seems also felt concerning the wisdom of attempting to pack important laws into small compass; but to this I plead that the axioms already stated by me are most of them purely Newtonian, and that for the attempt thus to summarise science in as few and simple statements as possible we have the high encouragement of his example. It is true that Newton issued his axioms in a form as perfect as it was reasonable or possible then to make them, and did not bring them out as matter for discussion. But to this two pleadings may be put in:—

(1) That their perfect form did not by any means *prevent* discussion, nor would it have been desirable if it had; it only made the inevitable discussion painful to him instead of pleasant.

(2) That in his day he was minting fresh coins, complete in design and workmanship, for the use of a race which possessed nothing of the kind; whereas now one is partly trying to rub off a little tarnish and furbish up old currency in more modern style, and partly trying to put into circulation a few fresh coins at a time when everybody feels that they have quite as much money as they want.

The step in advance which I believe has now to be made is the explicit introduction of the Ether into the scheme of physics. Newton knew well enough that a connecting medium was a philosophic necessity, but he did not see his way to asserting its physical existence and discovering its properties. Consequently his philosophy was all stated in terms of action at a distance.

But science has progressed since then, and the ether has become accessible in many then undreamed-of ways. It appears to me, therefore, that the time has come for enlarging the Newtonian axioms, on the basis of the labours of Faraday and Maxwell and of other men now living, and for fearlessly following up any consequences to which the new axioms may lead us.

My philosophic creed runs somewhat thus:—First that by our senses we become aware of *motion;* I don't much care by what sense it is, it seems to me by the muscular sense—partly eye muscles perhaps, mainly arm or leg muscles—but it may be by a succession of tactile sense-perceptions as some modern physiologists and psychologists believe. But none of these questions belong to pure physics: somehow or other we *are* aware of Motion and Time and Space. We had already erected the structure of Geometry without invoking motion and time, we now erect Kinematics. And by motion, which is a usefully vague term, I mean nothing less than the whole of kinematics.

Next in order of complexity we become aware of *force* plainly through our muscular or our tactile sense, and thus, indirectly, we gain the tremendously important idea of "matter." The *ratio* of force to motion is *inertia*; one of the most constant and fundamental qualities in the apparent universe. The *product* of force and motion is *activity*, whence arise the complex but brilliantly useful ideas associated with the term *energy*. In elaborating these we erect the whole science of Dynamics.

Thus far the scheme is essentially Newtonian, and the Newtonian axioms may be held to summarise its essentials in the briefest and clearest way. If I presume to restate them it is because the modern terms "acceleration" and "stress," which were not available for Newton's use, assist the expression, so that by their aid some minor difficulties, such as those caused by the phrase "uniform velocity and direction" disappear; this phrase need not have been introduced had a vector acceleration been a thing of easy apprehension or of common knowledge in Newton's time.

Prof. Minchin urges the explicit retention of the first law, not as a measure of time only, but as a qualitative statement introductory to the quantitative assertion of the second; and I fully agree. I should like to take the opportunity of thanking both Prof. Minchin and Prof. Henrici for their careful criticism of my Physical Society paper.

Premising that the necessary definition of terms must be understood or supplied, I now repeat from my former article the essence of the Newtonian laws.

Axiom 1. Without force there can be no acceleration of matter.

Axiom 2. The inertia of matter is unconditionally constant. [*Or*, Acceleration of matter is proportional to unbalanced or resultant force.]

Axiom 3. Every force is one component of a stress, and a stress in a body or system does not accelerate it.

Before proceeding, let me here intercalate a remark about the kind of *scholium* with which, on page 62 (NATURE, vol. xlviii., May 18) I prelude the definitions and axioms. I do not intend the "experimental results" there quoted to be used for teaching purposes; in fact, my present aim is in no respects pedagogic, but more ambitious; I quote them as affording some sort of experimental basis for the Newtonian axioms. An experimental basis is a necessity—in other words, an axiom must be based on some sort of experience; and the experience on which the Newtonian laws are based can hardly be considered as of a very commonplace type.

It is easy to *illustrate* the second law with bits of elastic and trucks on wheels, but it is not so easy to prove it with accuracy—the sort of accuracy attempted, for instance, in the case of the law of Ohm. It is customary to say that Astronomy proves it, but as a logical procedure that would be a terribly circular one; and besides, the nature of gravitation is so singularly unknown that it can hardly with satisfaction be used as a foundation stone.

Anyhow, the proof which by those experiments I *suggest* is, first to establish Hooke's law for a spring, statically, by weights, *i.e.*, to prove that force is proportional to displacement; next to show that vibrations of the spring are isochronous, *i.e.*, that acceleration is proportional to displacement; and thus to deduce that force and acceleration are proportional (in this case at any rate) to a high degree of accuracy. The difficulties, such as they are, of this proof are of a merely mathematical order, and are hence entirely unimportant.

The third "experimental result" quoted is only to suggest the impact experiments which Newton himself considered desirable as a basis for his third law.

One other point before proceeding. With regard to the claim for obviousness, or *prima-facie* certainty, sometimes set up in connexion with a long-known law of nature, on any such ground as that it is a mere assertion that Cause equals Effect:—may I say once for all, and quite impersonally, that such a claim appears to me to be metaphysical nonsense of the worst kind—the kind which has tended to bring real Metaphysics into unmerited disrepute. Is it not plain that everything depends on what is cause and what is effect, and that the interpretation of nature essentially consists in the discovery and accurate specification of what in any given case the true cause and the true effect are?

Now comes the new departure, or extension of the Newtonian axioms, so as definitely to include the medium which it has been one of the chief works of the present century to discover.

The chief axioms I intend to propose and trace the consequences of are:—

Axiom 4. A stress cannot exist in or across empty space.

Axiom 5. Material particles (atoms of matter) never come into contact.

Axiom 6. A stress must extend from one material particle to another: it cannot end in ether.

This last is hardly axiomatic, but it is based on special experimental evidence (Phil. Trans., 1893).

From these laws and from the law that stress is essential to activity (which last does not need a separate statement, being deducible from the Newtonian axioms), a series of what appear to me fundamentally important deductions may be made.

Some of these deductions relate to already known and admitted facts, while others introduce some as yet unknown or unadmitted: the former set are mostly referred to in my paper to the Physical Society, the others must be dealt with hereafter.

OLIVER LODGE.

MAY I make through your columns some criticisms on Prof. Lodge's views of dynamics, which I am afraid I failed to render intelligible to him during the discussion on his paper before the Physical Society?

It would be useless to say anything about his theory of "Contact Action," for he has rendered the whole discussion upon that point nugatory by saying in his reply to the criticisms that he does not admit that any two bodies can ever come into contact at all, *i.e.*, that the contact action he contemplates is something that takes place only between "the bodies" and an "ether" which exists between them. It follows that his own arguments and illustrations, as well as the criticism upon them, are all beside the point, for they all dealt with contacts between "bodies," not between a body and an "ether" in which it was moving. We must therefore begin *de novo*, and we must start this time with some definition or explanation of what he means respectively by "the bodies" and "the ether" which surrounds them.

But the point I particularly wished to discuss was his view of the "identity" of energy. I do not think any such identity can be recognised, at any rate if we grant Prof. Lodge's own hypothesis that energy on being transferred from one body to another is always transformed from Kinetic to Potential energy, or *vice versâ*, for I maintain that potential energy, as such, belongs to a system of bodies not to any particular one of them, and so has no local habitation even though it has a name.

The law of the conservation of energy is usually expressed by the formula—

$$\text{Kinetic} + \text{Potential Energy} = \text{Constant.}$$

But if this is to be a physical law, and not a mere truism, its terms must be defined in such a way that it is not a mere formal consequence of their definitions. As to Kinetic energy, everybody is practically agreed in defining it as $\Sigma\frac{1}{2}mv^2$, or, which is the same thing, as $\Sigma\int mvdv$. But if we define potential energy, as Prof. Lodge would apparently have us do, as $\Sigma\int -Fds$, the formula does not assert a physical fact—at least no new one—but is merely an identity. The equation of energy in this form would, indeed, be quite useless, for we should have to know the previous path of each particle in order to evaluate $\int Fds$. And so we find that in the equation of energy, as used by mathematicians, the "Potential Energy" has nothing to do with any paths the particles may have described, but is a mere function of their present co-ordinates.

The truth is that the physical fact implied in the law of conservation is not that the *energy in general* is conserved throughout all changes in the system, but merely that the *kinetic* energy is always the same whenever the system returns to the same configuration; that term being held, if necessary, to include, not only geometical form, but such conditions as temperature, chemical or electrical state, &c.

The law of energy is then better stated thus: "In any independent system of bodies—

Kinetic energy + A function of the configuration of the system = Constant."

And we may, if we like, call this function "Potential energy," since it diminishes as the kinetic energy increases; but we have no right to assume *à priori* that it is the same sort of thing as kinetic energy. It is true that in some cases what used to be called potential energy is now regarded as in great part kinetic, but this can only be done if at the same time we change our conception of the "configuration" of the system. If we regard the energy stored in a reservoir of compressed air as kinetic instead of potential, we must include the average positions of its particles in our statement of the configuration of the system.

But the important conclusion to be drawn from this is that potential energy (*quâ* potential) does not belong to a single particle but to the system as a whole, or at least it can only be allocated to such portions of the system as may by themselves be regarded as independent systems. If ever all energy were explained to be kinetic energy, and if we could then explain how it comes to be transferred from one body to another, we might be able to trace the biography of a piece of energy as we might that of an atom of matter. But even if "potential energy" may thus be regarded as only a name used to veil our present ignorance of what has happened to the kinetic energy, it is still illogical to talk of the "identity" of energy till this veil has been removed. And I cannot see that anything Prof. Lodge has said helps us in the smallest degree to remove it.

On the Velocity of Propagation of Gravitation Effects.

IF, according to the accepted kinetic theory of gases, the velocities of molecules "vary between zero and infinity" (Maxwell): it must certainly result that frequently enormous velocities are accidentally attained by even gross molecules, and this produces no perceptible disturbance measured by us. It would be admittedly almost puerile to ask how high a velocity might normally be possessed by a large number of particles of matter (as an *à priori* question, that is), provided the particles be perfectly elastic, so that there is no jar at their encounters, but the movement goes on with perfect smoothness, so that its existence may escape detection by the senses. Moreover there is no resistance in space to free motion of material particles.

In regard to the effects of gravity then, the practical question for us (in regard to their elucidation) becomes, What is the velocity demanded for the transmission of gravity? This velocity, whatever it be (if very great, but finite), may then reasonably be considered to exist in matter in some form, or to be possessed by it. To assert *à priori* that the existence (say among particles of matter) of a velocity even many times that of light, is unlikely, or to view this with incredulity as an abstract fact apart from its possible utility—would seem to partake somewhat of the nature of a prejudice, due possibly to absence of adequate reflection.

A high normal velocity has the undoubted mechanical advantage of being able to produce a given dynamical effect by means of very small particles, *i.e.*, without demanding for such effect any large collective mass or the employment of a great quantity of material. Smallness in size moreover allows the particles to possess a very long mean path: and they have the advantage of occupying, *in toto*, very little room (although they may be relatively numerous).

Without going into the question of the *modus operandi* of such effects as explosions of gases, dynamite, &c., it at least appears manifest that by the rejection of "action at a distance," a store of motion of a very high intensity in the matter of space would be consistent with, or would be demanded in order to give some rational account of sudden developments or transferences of motion. It may appear questionable whether a normal velocity of matter in space only equal to that of light, would be sufficient to account for the explosive violence of somt transferences of motion. The rate of travel of light when viewed in relation to the intervening distances of the chief bodies of the universe—may appear even slow. More than three years, for instance, are occupied in the transmission of a wave from the *nearest* star to our system.

It may be reasonable then to assume that the possibilities for the existence of a higher rate of intercommunication than this (that of luminous effects) may exist in nature, and that the bodily mass movements of the units of the universe may influence each other more quickly than their molecular movements; since gravitational disturbances or their measures appear to demand this. It is so far certain that in addition to the luminiferous ether there may be plenty of room for finer and therefore more mobile material: or no one, as far as I am aware, has urged a difficulty on this head, provided its presence were subservient to some great mechanical purpose.

Hamburg, May 16. S. TOLVER PRESTON.

Singular Swarms of Flies.

IT may interest some of your readers if I describe a sight which I saw this forenoon, which was quite new to me and apparently to all who witnessed it. After a brisk N.N.E. breeze in the morning, at about 11 a.m. it fell flat calm, the sky becoming inky black, with every sign of a heavy thunderstorm impending. Soon after, looking out of my office window at a belt of trees some hundred yards away, my eye was caught by a most singular and to me (at first) uncanny sight.

Above the trees, apparently one on each principal prominence of their outline, there appeared a number of slim clouds, like straight wreaths of thin smoke, slanting upwards into the sky. Though they maintained their positions, they seemed alive and moving, in a manner partly suggestive of the twisting motion of a waterspout. A field-glass showed the clouds to be swarms of small flies; and looking around, similar swarms were seen above all the trees everywhere. They were perfectly visible to the naked eye a quarter of a mile off, and the glass showed them on the furthest trees in sight, these being nearly a mile away. All seemed to have much the same peculiar slant, pointing more or less towards the (then invisible) sun. Some of the swarms looked to be fifteen or twenty feet long.

Over a few of the low bushes on a bank of rough ground close by, similar swarms were to be seen. Even these, however, were inaccessible; but I caught some of an apparently similar swarm drifting over the ground between the bushes, and inclose some of the specimens herewith. To me they look just like the insects which ordinarily strew one's table under the lamp at night (I notice, by the way, that to-night there are none, though the window is open as usual), and therefore I am led to suppose that the special character of the swarms noticed to-day appertains to some condition of the atmosphere, and not to the species of insect; but perhaps some of your contributors can throw light on this point. It would also be very interesting to know whether similar swarms were noticed elsewhere to-day, and whether they showed the same slant as was noticed here.

R. E. FROUDE.

Admiralty Expt. Works, Haslar, Gosport, May 27.

P.S.—The swarms of flies disappeared about 1 p.m., as the thunder clouds cleared away.

Popular Botany.

WE do not expect accurate scientific information from journalists; but so much confusion and error are seldom compressed into a small space as are to be found in a paragraph of which I send you extracts, cut from a London daily:—"A sad case of accidental poisoning by wild hemlock is reported from Tyne Dock. A little band of school children playing on some waste ground had gathered a quantity of a common variety of this dangerous plant, known to country folk as 'fool's parsley.' According to the evidence of one of the party, a little girl aged eight named Pringle, her sister 'said it was cabbage, and she should eat some.' Another boy and girl, named Shafter, who were still younger, followed her example. All three were soon afterwards taken ill. One 'complained of her legs as if they were tired'—a common symptom of hemlock poisoning—and 'her head afterwards got bad.' Pringle ultimately recovered under treatment, but the two Shafters on reaching home gradually became unconscious, and died the same afternoon within twenty minutes of each other. This species of hemlock, known to science as the *Conium maculatum*, is said to be much more poisonous in May than in any other month." It would be interesting to know what the plant really was. It can hardly have been the true hemlock, *Conium maculatum*, and instances of fatal poisoning by fool's parsley, *Aethusa cynapium*, are so rare that an authentic record would be valuable. It is difficult to imagine either of these plants being mistaken for cabbage. Can it have been *Cicuta virosa* or *Oenanthe crocata?* It would be interesting if any reader of NATURE could throw light on the subject.

The following delightful paragraph is cut from the same paper a few days later:—

"Can plants see? Darwin gave it as his opinion that some of them can [one would like to know where], and an Indian botanist relates some curious incidents which tend to verify the belief. Observing one morning that the tendrils of a convolvulus on his verandah had decidedly leaned over towards his leg as he lay in an attitude of repose, he tried a series of experiments with a long pole, placing it in such a position that the leaves would have to turn away from the light in order to reach it. In every case he found that the tendrils set themselves visibly towards the pole, and in a few hours had twined themselves closely round it."

ALFRED W. BENNETT.

Gaseous Diffusion.

IN your Notes of last week there is a description of an experiment for showing gaseous diffusion, devised by Prof. v. Dvorák, which, however, does not seem so striking as one that was shown at the Royal Institution more than twenty years ago by, I think, Dr. Odling.

A cylindrical porous battery cell was closed by a cork through which passed a vertical glass tube of about half an inch in diameter. The lower end of the tube was bent upwards into the form of a delivery tube, and was placed in a pneumatic trough, with a cylinder filled with water inverted over the end of the tube. On placing an inverted bell-jar of hydrogen over the porous cell, gas was rapidly collected in the cylinder, and this contained sufficient hydrogen to explode on the application of a flame. On removing the bell-jar, the hydrogen diffused outwards, and water was drawn up the wide tube.

Cooper's Hill, May 29. HERBERT MCLEOD.

NOTES UPON THE HABITS OF SOME LIVING SCORPIONS.

THE literature which treats of the habits of living scorpions is not voluminous, but it labours under the disadvantages of being based largely upon undetermined species, and of being often of questionable trustworthiness with regard to the statements that are made. Even accounts that have been given of late years of the same species of scorpion differ widely as to facts of no small importance. Mons. L. Becker, for instance, asserts that the senses of hearing and seeing are highly developed in *Prionurus australis*, the thick-tailed yellow scorpion of Algeria and Egypt; Prof. Lankester, on the contrary, declares exactly the opposite to be the case. Discrepancies such as these and the deficiencies above mentioned show the need for fresh observations upon the subject, and no further excuse need be offered for publishing the following notes upon the habits of some specimens of two species of scorpions, *Parabuthus capensis* and *Euscorpius carpathicus*, which I was fortunate enough to keep for some months in captivity.

For the specimens of Parabuthus I gladly take this opportunity of expressing my thanks to my friend Mr. H. A. Spencer, of Cape Town, who kindly collected them for me at Port Elizabeth, while acting as medical officer on board the Union Steam Ship Company's s.s. *Mexican;* while for the Euscorpius I am indebted to the kindness of Dr. Gestro, of the Natural History Museum at Genoa. This last genus of scorpion Prof. Lankester has also written about; many of my observations, therefore, merely confirm those of this author. No description, however, has to my knowledge ever been published upon the habits of any species of Parabuthus. This genus, however, belongs to the same family as Prionurus, and the behaviour of the two in captivity seems to be very similar.

There is an abundance of evidence that scorpions are nocturnal, and mine were no exception to the rule. They would spend the daytime huddled together in corners of their box or under pieces of wood; at night they would wander about, presumably in search of food. It was easy, however, at any time during the day to rouse them from their sluggishness by applying a little artificial warmth to the box. One end of the box containing the Parabuthus was closed with a plate of perforated zinc. If this box was placed in the fender at a distance of about a couple of feet from a moderate fire, with the zinc end turned towards the grate, the scorpions would climb upon the metal plate and bask in the warmth. But immediately the box was brought near the bars of the grate they would all clamber or tumble from their position with ludicrous haste. It must not be supposed, however, that the amount of heat required to make them retreat was at all great. As a matter of fact warmth that I could without inconvenience bear for several minutes upon my hand would throw these animals at once into a state of the greatest consternation.

When walking both Parabuthus and Euscorpius carry the large pincers or chelæ well in advance of the head; these appendages thus fulfil the office of antennæ or feelers. In Parabuthus the body, however distended and heavy with food, is raised high upon the legs exactly as Prof. Lankester has described in Prionurus, and the tail is usually carried, curled in a vertical plane, over the hinder part of the back. In Euscorpius, on the contrary, as has also been pointed out by Prof. Lankester, the ventral surface of the body is scarcely raised from the ground during progression, and the tail, which is very slender and relatively much lighter than in Prionurus or Parabuthus, is dragged along, extended, and with a slight curl only at its hinder end. This difference in the carriage of the tail depends possibly upon the difference in its size and weight. For it seems reasonable to suppose that the heavy, robust tail of a Parabuthus or Prionurus is carried with less muscular effort when curled over the back than when stretched out behind as in Euscorpius.

When attempting to climb up the smooth sides of their box the Parabuthus would raise themselves upon the extremity of the fifth segment of the tail, and by keeping this organ perfectly rigid and in the same straight line as the body they could maintain themselves in a nearly vertical position, thus reaching considerably higher than if supported upon the hind legs alone.

The method of digging shallow pits or holes in sand, which Mons. Becker and Prof. Lankester have described in the case of Prionurus, is also practised by Parabuthus. Standing upon the first and fourth pairs of legs, and using the tips of the chelæ and the end of the tail as additional props, with the disengaged legs a scorpion rapidly kicks the sand backwards between the legs of the last pair, very much as a rabbit or rat does when burrowing. Then with the apparent intention of removing what would prove an obstacle to its vision when crouching in the hole, it sweeps aside with its tail the heap of sand that has been thrown up, until the area surrounding its lurking place is tolerably level.

I never saw a Euscorpius digging in the sand. They were usually to be found during the daytime under pieces of wood, to which they were nearly always clinging belly uppermost. It is difficult to explain why this attitude should be assumed. Many terricolous arthropods, however, have the same habit, and I see no reason for thinking that in the case of Euscorpius it has any connection with the copulation of these animals as Prof. Lankester suggests.

All scorpions appear to be carnivorous, and there seems to be little doubt that they live principally upon insects or other articulated animals. My specimens of Euscorpius would eat blue-bottles and small flies, small cockroaches (*E. germanicus*), wood-lice, small spiders, and centipedes (*Lithobius* and *Geophilus*). The Parabuthus were fed principally upon the common house-cockroach and upon blue-bottles. It is interesting to note in connection with this last fact that Prof. Lankester's examples of Prionurus would not eat this common cockroach, nor did they seem to care for blue-bottle flies. This difference of instinct in the choice of food is remarkable, seeing how similar these two scorpions are in other particulars, both of habit and structure.

No one acquainted with the agility of a cockroach and the usual sluggishness of a scorpion would think that the latter would often succeed in capturing the former. Yet in truth, when placed in the same box, the insect seldom has a long lease of life. Its ultimate fate is always due to its ignorance of the scorpion's nature, and to the latter's adroitness in seizing anything that comes within reach. Wandering round the box, and exploring every inch of its new quarters with its antennæ, the cockroach soon discovers the presence of the scorpion by touching it with the tips of these organs. The scorpion's sense of touch, however, is as delicate as the insect's, and the latter's antennæ, or any part of it that happens to be near, is quickly seized by the pincers of the scorpion. Should the latter be disinclined for food and take no notice of the cockroach's first approach, the insect, continuing its wanderings, will fearlessly creep over the scorpion, just as a rabbit will over a python. Obviously this fearlessness must prove its destruction in the end, if not immediately. By means of its agility and strength, a cockroach sometimes eludes the scorpion's first clutch, and sometimes, but not often, breaks away from the latter's hold. But it does not readily learn from its narrow escape the advisability of giving its enemy a wide berth the next time they meet.

Although usually trusting to their heels for escape, cockroaches occasionally resort to a method of self-defence which is sufficiently curious to be described. Advancing upon an adversary rear end foremost, and at the same time wagging from side to side this region of the body, they deliver vigorous backward kicks with their spiny hind-legs. This novel and humiliating mode of fighting, although not likely to prevail long against jaws and stings, is sufficient, nevertheless, to gain sometimes for the insects a temporary reprieve. I have indeed seen a fine female Madeira tarantula spider retreat in discomfiture before a big cockroach of the same sex, which assaulted her in the way described.

As soon as a cockroach is seized the use of the scorpion's tail is seen; for this organ is brought rapidly over the latter's back, and the point of the sting is thrust into the insect. The poison instilled into the wound thus made, although not causing immediate death, has a paralysing effect upon the muscles, and quickly deprives the insect of struggling powers, and consequently of all chance of escape. If the insect, however, is a small one, one in fact that can be easily held in the pincers and eaten without trouble while alive, a scorpion does not always waste poison upon it. Thus I have seen a Parabuthus seize a blue-bottle fly, transfer it straight to its mandibles, and pick it to pieces with them when still kicking. Prof. Lankester only rarely saw his scorpions feed. I was more fortunate and repeatedly watched the operation, which is always performed exactly as this author has described. An insect is literally picked to pieces by the small chelate mandibles, these two jaws being thrust out and retracted alternately, first one and then the other being used. The soft juices and tissues thus exposed are drawn into the minute mouth by the sucking action of the stomach. It would seem, however, that some hard chitinous pieces are also introduced into the alimentary canal, for the entire exoskeleton of a cockroach is rarely, if ever, left after the meal is finished.

Feeding is a slow process; a good-sized cockroach will last a Parabuthus for upwards of two hours or more. But although voracious eaters when the chance presents itself, they are able to endure with impunity starvation of several weeks' duration. Unlike spiders, which are notoriously thirsty creatures, scorpions never seem to need anything to drink. At least none of mine were ever seen to touch water, although a supply of it was at first always kept in their box.

With regard to the higher senses, the only one that seems to be highly developed is that of touch. Mons. L. Becker declares that sight and hearing are excessively developed; but I cannot substantiate this statement in either particular. With regard to hearing, my observations agree entirely with those of Prof. Lankester, who could not detect the existence of any sense of this nature. None of my scorpions ever gave the slightest response to any kind of sound, although they were tried with tuning forks of varying tone and with shouts of both high and low pitch. These animals, in fact, resemble the hunting spiders in being apparently devoid of auditory organs. They further resemble them in the development of their visual powers, being able to see a moving body, like a living cockroach, at a distance of only about three or four inches. Even at a distance less than this they do not seem able to distinguish form. Thus a specimen of Parabuthus excited by the presence of cockroaches in the box, was seen to rush at one of its fellows that crossed its line of vision about two inches off, evidently not recognising by sight a member of its own species, for directly the pincers came in contact with the latter the mistake was discovered, the pugnacious attitude dropped, and no further notice was taken. This last observation shows that more is learnt from the sense of touch than from that of sight, an inference which is further supported by the habit, above referred to, of carrying the pincers well in front of the head as if to feel the way. There is no doubt that the external organs of touch in scorpions are the hairs which thickly or sparingly cover various parts of the body. The tail is often very thickly studded with setæ, and the poison vesicle always has some upon it. Their use upon this latter organ is very plainly seen during the act of stinging. For this act is not by any means a random thrust delivered indiscriminately at any part of a captured insect. On the contrary, a scorpion generally feels carefully for a soft spot, and then with an air of great deliberation delicately inserts its sting into it. There can be little doubt that this care is taken that there may be no risk of damaging the point of the sting against a substance too hard for it. A reckless stab against the resisting chitinous exoskeleton of a beetle, for instance, might easily chip this point and thus deprive the scorpion of its most efficient weapon of attack and defence. The same care of the sting is shown in the carriage of the tail, this organ being curled in such a way that the point cannot come into contact with any foreign bodies. Even when teased with a piece of stick or irritated by being crawled upon by a cockroach, a scorpion is not often sufficiently provoked as to use the sting. The tail is certainly used to knock aside the instrument or sweep off the insect, but the sides or lower surface of the organ are employed, the vesicle being carefully tucked down. Upon one occasion a Parabuthus was seen to kill a cockroach and retire to a corner to eat it in peace, beginning at the tail end. Presently a smaller example of the same species coming along and finding the opposite extremity of the insect disengaged, started feeding on its own account. So quietly was the process carried on by the two, that not until nothing but a few shreds remained did the larger discover the presence of its messmate. Thereupon it quickly brought its tail into use and by beating off its unwelcome guest secured for itself the remains of the meal. But although the provocation was great the defrauded one never attempted to use its sting to punish the intruder.

In connection with the organs of touch, the pectine or ventral combs must not be forgotten. Of the function of these appendages something is known, though no doubt much remains to be learnt. Their situation near the generative aperture, their larger size in the males, and the modification of their basal portion in the females of some species, *e.g.* Parabuthus, suggest that they are tactile sexual organs of some importance, and Gaubert's discovery of the nervous terminations in the teeth is a satisfactory confirmation of this supposition. But apart from sexual functions it is highly probable that they are useful organs of touch in other relations of life, enabling their possessor to learn the nature of the surface over which it is walking. In favour of this view may be adduced the fact that these animals have been seen to touch the ground with their combs. Moreover, it is a very noticeable circumstance that scorpions which, like Euscorpius, creep along with their bellies close to the ground, have very short combs; while in others which, like Parabuthus, stand high upon their legs, the combs are exceedingly long. I once noticed a Parabuthus marching over a piece of a dead cockroach. When she had half crossed it, instead of going straight ahead as was expected, she halted abruptly, backed a little, and, stooping down, started to devour the fragment. From the height at which the body was being carried, I am persuaded that no portion of its lower surface, except the combs, could have come into contact with the piece of food; so there can be little doubt that its presence was detected by means of the organs in question.

Creatures which, like snakes, are both carnivorous and venomous, and present at the same time an appearance which is by no means reassuring, are always held in bad repute by mankind in general, and suffer in accordance with the principle laid down in the adage, "Give a dog a bad name and hang him." But amongst creatures of this description it is probable that scorpions qualify for first place with respect to the number and enormity of the vices with which they have been charged. Those that are most frequently alleged against them are general ferocity, murder, cannibalism, infanticide, and suicide. And yet in spite of this serious charge-sheet, there is no doubt that they are much-maligned animals. For in defence of the accusation of ferocity I can say that I never saw a scorpion use its destructive weapons except with the legitimate object of killing prey for purposes of nutrition, or as a reasonable means of defence when molested. Naturally enough they will not tolerate handling, but when allowed to crawl upon the hand they make no attempt to sting it, and merely evince a desire to escape to surroundings more natural and congenial than human skin. From the charges of cannibalism and murder, however, these animals cannot be so easily cleared. For there is an abundance of evidence that they do sometimes, when in captivity, both kill and eat each other. Nevertheless, so far as my experience goes, members of the same species do for the most part live together in perfect harmony. Once only did I see a large Euscorpius eating a small one. But since the latter showed no signs of violence, there are no reasons for supposing that it had died other than a natural death. Like many other animals, scorpions may be made to fight by artificial means, and when roused to a high pitch of excitement by too much heat, they will clutch and grab at each other with the appearance of the greatest ferocity. But I never saw any evil result from these tussles. The combatants always seemed to prefer to part company without bloodshed.

As for the accusation of infanticide, it appears to be quite groundless. For it is well known that a mother-scorpion protects her young by carrying them about on her back until they are able to shift for themselves.

The question as to whether scorpions do or do not commit suicide by stinging themselves to death, when placed in a circle of fire, or otherwise tortured by that element, is one which has excited a considerable amount of discussion. The belief that they do do so, with the object of escaping from the pains of burning, is of long standing, and probably has many adherents at the present time. But the experiments of Mr. Bourne upon some Madras species have shown (firstly) that the poison has no effect upon the scorpion that possesses it, nor yet upon a member of the same or of a closely allied species, and (secondly) that these animals are easily and quickly killed by a moderately warm temperature (50° C.). Moreover, when distressed by a too warm atmosphere, or, according to Lankester, by chloroform vapour, these animals have a habit of waving their tails in the air and of thrusting the sting forwards over the head, as if to punish some unseen enemy. And if the sun's rays be focussed with a lens upon the back of a scorpion, the animal immediately brings its tail over, and attempts to remove with it the cause of irritation. So that the true account of at least some of the so-called cases of suicide by scorpions seems to be this: the animals in reality have died from the heat to which they were exposed, and the observers have erroneously inferred that the thrusts of the tail were intended to put an end to the animal's sufferings. My own experiments are all in favour of this conclusion. I held a specimen of Euscorpius in a corked test-tube over a low fire. As soon as the air in the tube began to grow warm the animal, apparently in great distress, struggled about the confined space for a few seconds, brandishing its tail the while, then lapsed into insensibility. The glass of the tube at this period was only slightly warm to my hand. Taken out of the tube and placed near an open window, the animal quickly revived; but it died the third time the experiment was tried. On no occasion, however, did it attempt to sting itself. I also experimented upon Euscorpius and Parabuthus by focussing the sun's rays upon them, and by placing mustard upon the membrane between the plates of the back. Both the species attempted to remove the cause of irritation by scraping at the burning spot with the sting of the tail; but they seemed particularly careful not to sting themselves.

There seems, however, to be sufficient evidence to prove that some scorpions have been seen to sting themselves during the course of experiments of a nature similar to those described above. One observer indeed mentions, in the case of an Indian scorpion, that blood issued from the wound made by the sting—a piece of corroborative detail which enhances the probability of the accuracy of the observation. But it is *à priori* improbable that the scorpion has any intention of killing itself. It seems, however, not improbable that a random blow meant for an unseen enemy might accidentally strike and pierce the deliverer; or that when the irritation is localised, as in the cases of burning with a lens, acid, whisky,[1] or mustard, the scorpion, failing to remove the substance by the ordinary means of scraping with the tail, might thrust its sting into the spot affected, with the intention, not of killing itself, but of destroying the agent that is causing the pain. Or, indeed, it is conceivable that the mental faculties are so deranged by torture and the approach of death, that the scorpion does not recognise its own body by its sense of touch, and stings it as it would sting any other object within reach of its tail. If a blow inflicted in either of these ways were to pierce the brain, or were to seriously lacerate the great dorsal blood-vessel, it might, one can suppose, cause death of itself, independently of the burning.

So that if it be admitted that scorpions have sometimes killed themselves, our verdict, it would seem, must be—accidental suicide, or suicide while of unsound mind.

R. I. POCOCK.

[1] It is stated that in some parts of N. America scorpions sting themselves to death if a drop or two of whisky be placed upon their backs; and that from this manifestation of their dislike of alcohol, these animals are known to the natives as teetotallers.

NOTES.

WE greatly regret to have to record the death of Dr. Charles Pritchard, F.R.S., Savilian Professor of Astronomy at Oxford. He died at Oxford on Sunday morning last in his eighty-fourth year. We hope to give on a future occasion some account of his career as a man of science.

THE gold medal of the Linnean Society has this year been awarded to Prof. Daniel Oliver, of Kew, to whom it was presented at the anniversary meeting of the Society held at Burlington House on the 24th inst.

A TABLET erected in Truro Cathedral to the memory of the late Prof. John Couch Adams was unveiled by the Bishop of Truro on Saturday last. Canon Mason, a companion of Prof. Adams at Cambridge, delivered an address, in which he spoke of the illustrious astronomer as "one of the greatest of Cornishmen." The tablet—the cost of which has been defrayed by public subscription—was designed by Mr. Pearson, R.A., and executed by Mr. Juleff, sculptor, of Cornwall. The Latin inscription, a translation of which will be placed near the tablet, is by the Archbishop of Canterbury.

THE new engineering and electrical laboratories at University College, Gower Street, were opened on Monday last by the Duke of Connaught. Many invited guests were present at the ceremony. Mr. J. E. Erichsen, the president of the college, in beginning the proceedings, said it was confidently anticipated that when the two laboratories which were about to be opened were fully equipped with mechanical appliances and electrical apparatus the college would possess every requirement for advanced research and thorough teaching. The cost would not fall far short of £20,000, and the council hoped that a liberal response would be made to the appeal for funds which had been issued, and especially that the great City Companies, which had done so much for education and were so deeply interested in the success of such an enterprise, would give their assistance. Engineering was all-important, not only from a scientific, but from a national point of view, and it was needless to dwell on the importance of increasing the opportunities of the youth of this country for the study of the wonderful science of electricity, which half a century ago was little more than a toy for the learned, but now, through the telegraph and the telephones, entered into the daily life of us all, and before which gas was, it would seem, destined to "pale its ineffectual fires" as an illuminant. It was to be hoped that such laboratories as these would lead to fresh scientific triumphs and further practical developments. The Duke of Connaught, before formally declaring the laboratories open, delivered a short address, in the course of which he said it had been his good fortune to see some of the greatest engineering works in different parts of the Empire, and he was certain that those who, like himself, had seen them would recognize the vast importance of a thorough study of the sciences on which they reposed. Foreign nations were competing with us on all sides, and if we were to maintain the proud position which we had hitherto held we should have to use every endeavour to increase the opportunities of study and of practical work. He trusted that the ceremony of to-day would mark a new era in the history of the college, and would tend to the prosperity and the increased power of engineering in this country.

THE death of Prof. Ernst Eduard Kummer is announced. He died at Berlin on May 14. Dr. Kummer was a Foreign Member of the Royal Society, and at the time of his death was in his eighty-fourth year.

A MEMOIR of the late F. A. Genth was read at a recent meeting of the Chemical Section of the Franklin Institute, and will be published in the June number of the Institute's Journal. It was prepared by a committee specially appointed for the purpose. Mr. Genth is described in the paper as one of the ablest mineralogists, and certainly the foremost mineral analyst, hitherto known in the United States. The writers also speak in high terms of his personal character, and of his remarkable power as a teacher.

MISS AGNES CRANE writes to us from Brighton with regard to an intimation she has just received from the "chief commissioner (Geology) of the Women's Auxiliary Branch of the World's Congress." It is to the effect that the last week in August has been set apart, for a short session during the day, for the presentation of specially-prepared geological papers by women. Such papers are not to exceed half an hour in reading. The co-operation of English workers in this science is invited, and an address to "geological women" will shortly be issued. The chief commissioner in geology is Mrs. Louisa F. Lowery, of 11, Gainsborough-street, Boston, Mass.

A GEOLOGICAL excursion to Dorking will be made by members of the Geologists' Association on Saturday, June 3, under the direction of Prof. Boulger and Mr. T. Leighton, the object being to examine the district described by the directors in a paper read before the Association on December 2, 1892. Arrangements for excursions on the remaining Saturdays of June have also been made.

THE following prize subjects have been recently announced by the Belgian Academy for 1894:—A. Mathematics and Physics. (1) Exposition and discussion of the various theories of diffusion of one liquid into another, with new facts bearing on this; (2) Estimate of theories explaining the constitution of solutions; new experiments throwing light on the subject, and especially on the existence of hydrates in aqueous solutions; (3) The investigations of modern geometers on the theory of the triple orthogonal system to be summarised and extended in some important respect. B. Descriptive Sciences. (1) New researches on the intervention of phagocytosis in the development of invertebrates; (2) Description of the phosphate, sulphate, and carbonate minerals of the Belgian region, with indication of beds and localities; (3) New researches on the peripheral nerve-system of Amphioxus, and especially on the constitution and genesis of the sensitive roots; (4) New researches on the mechanism of cicatrisation in plants. The prize in each case is a gold medal worth 600 francs. Further, the Jean Servais Stas prize of 1,000 francs is offered for new researches determining the (at present uncertain) atomic weight of one or several elements. Memoirs may be written in French or Flemish, and must be sent in, with motto, &c., before August 1, 1894. Only manuscripts are allowed.

AT the time of our last issue an anticyclone from off the Atlantic was spreading over the south-west of this country, and caused a renewal of the drought in many places in the south and east of England, but in Scotland and the north of Ireland the conditions were less settled, and a moderate gale was experienced in the north of Scotland. The maximum day temperature ranged during the first part of the period from about 55° in some parts of the north to 74° in the extreme south, while the night minima were generally high for the season. During the early part of the present week the barometer continued high, but several small depressions formed over the south and east of England; cold northerly winds spread over the whole kingdom, accompanied by rain in many districts, and adecrease of several degrees in the temperature, the shade thermometer falling to the freezing point in the north of Scotland during the night of May 29. The *Weekly Weather Report* of May 27 showed that the temperature for that period was again above the mean, the average excess being from 3° to 5°. Rainfall was rather more than the mean in the north of Scotland, but less in all other districts. Bright sunshine was more prevalent over England and parts of Scotland than in the previous week; in most parts of England the percentage of possible duration was from 41 to 46, while in Ireland it was 19 to 20, and in the north of Scotland only 17 per cent.

DR. J. HANN has published in the *Sitzungsberichte* of the Vienna Academy of Sciences some of the results of the anemometrical observations made at the Meteorological Institute at that place from 1873 to 1892. The discussion, which occupies eighty octavo pages, is divided into three sections: (1) the daily period of absolute wind velocity (without regard to direction), (2) the yearlyperiod of the velocity, and (3) the yearly period of the direction. In the two first sections a comparison of similar results for other stations, partly specially calculated for this purpose, has been made. The following are a very few of the results of Dr. Hann's valuable and elaborate work. The wind velocity shows a principal single daily period, with a minimum at 6h. a.m., and a maximum at 1h. p.m. Another secondary minimum is exhibited at 7h. 30m. p.m., and is followed by a secondary maximum at 10h. p.m. The cause of these secondary extremes is found to lie in the daily range of stormy winds; on calm days the secondary extremes disappear. The absolute mean maximum velocity occurs in March, about 14 miles per hour, and the minimum in October, about 10 miles per hour. There also appears to be a secondary maximum in November, and a secondary minimum in January, while from spring to summer there is again a slight increase in the velocity. With regard to direction, the northerly component has its maximum in March and its minimum in October, the easterly component has its maximum in April and minimum in July, the southerly component has also its maximum in April and its minimum in June and, lastly, the westerly component reaches a maximum in July and a minimum in February.

THE Royal Observatory of Turin has recently published a work on the climate of that place, prepared by Dr. G. B. Rizzo, which is based on one of the longest series of observations extant. The monthly means and extremes of temperature and summaries of weather are given for 138 years (1753–1890), and the monthly means and extremes of atmospheric pressure for 104 years. The climate of Turin is of the Continental type, but is not very severe, as the mean difference between the hottest and coldest months is only 40°. The mean for January is 33°, and for July 73°; the mean of the annual minima is 13°, and the maxima 93°. The average number of days with rain and snow is 106, and the amount 33 inches. As this long series offers facilities for the investigation of secular variations, Dr. Rizzo has endeavoured to determine the periods of recurrence of hot and cold years. He finds that the observations do not support the period of thirty-five years quoted by Brückner, but that the hot and cold years succeed each other at intervals of about nineteen years. The causes which produce these variations are unknown, but they appear to depend upon local, rather than upon any extra-terrestrial conditions. The years of most rainfall are the coldest, but the series shows no sign of the climate changing, as some persons have imagined.

IT is well known that the population of France is made up of many different elements, including, among others, Aquitanians, Ligurians, Gallic and Belgic peoples, Franks, Burgundians, and Norsemen. The Paris Society of Anthropology is strongly of opinion that much might be done to distinguish these various elements from one another, and has accordingly issued a circular in which it indicates to local observers the points about which information is wanted. These relate both to living persons and to human skeletons, or parts of skeletons, found in ancient monuments and elsewhere. Such remains, if there are no local buildings in which they can be placed, will be received by the Society and preserved in its museum.

M. A. DE MORTILLET contributes to the *Bulletins de la Société d'Anthropologie de Paris* (No. 1, 1893) an interesting note on Manx cats. He points out that the Isle of Man is not the only part of the world in which tailless cats are found. They are very common on the coasts of Japan, and have been cleverly represented by Japanese artists. M. de Mortillet suggests that Manx cats may be descended from specimens brought to the Isle of Man from Japan by sailors.

DURING a recent stay at Buitenzorg, in Java, Herr Haberlandt made some experiments in the Botanical Gardens there, on the transpiration of tropical plants. In general this was found considerably less than that of plants in Central Europe. Thus of seventeen tropical species, some with coarse, leather-like, others with tender, leaves, nine species transpired per day and per square decimeter surface less than 1 gramme; in six the amount was between 1 and 2 gr.; and in two only it reached 2·6 and 3·25 gr. Now, with European vegetables and woody plants it varies commonly between 2 and 5 gr., and sometimes reaches 6 or 7 gr. or more. This result the author considers a strong argument against the view that the transpiration current is of first importance in nutrition of land plants. These tropical plants, with their small transpiration, show extremely luxuriant vegetation, and are able, through osmotic forces, doubtless, to convey nutritive salts to their highest parts. It is curious that, spite of the great humidity of the air and the large amount of water in the ground, these plants often possess guards against too great transpiration, such as thick, cuticularised epidermis, deeply sunk stomata, and especially tissues adapted for storage of water. And the reason cannot lie, as sometimes at the coast, in the presence of salt in the ground. Herr Haberlandt finds an explanation in the fact that while he total transpiration is comparatively small, the hot sunny forenoons may occasion large evaporation. The transpiration in a forenoon hour was, in general, four to twelve times that in an afternoon hour; sometimes as much as twenty or thirty times. The forenoon hours are by far the most favourable to assimilation, and it is most important to the plant that its turgescence be not then too much depressed, an end accomplished through those water reservoirs.

THE last issue of the memoirs of the Novorossian (Odessa) Society of Naturalists (vol. xvii. 3) consists of a very elaborate work in French, "Monographie des Turbellariés de la Mer Noire," by Dr. Sophie Pereyaslawzewa, ex-director of the Sebastapol Biological Station. The title of the work does not, however, exactly render its contents, as the author has not only given a monograph of forty-five species of Turbellariæ from the Black Sea, of which twenty-nine species and the genus, Darwinia, are new; she deals also with the anatomy and embryogeny of the Turbellariæ, and presents them in a new light. The striking likeness between a young Acœla and an Infusorian—she says—must probably be considered as the cause of the many errors committed as regards the Turbellariæ altogether. Various authors have differed immensely in their description of the Acœla; some have found in it no digestive cavity, others have denied the histological differentiation of the teguments; others, again, have denied the existence of a nervous system. It might have seemed that such instances would soon have been dissipated when carefully-prepared sections were resorted to; but the sections, made by different explorers, seemed to support the same views, as known from the works of Graeff and Goethe. Mrs. Pereyaslawzewa now maintains, and supports her affirmations by carefully-prepared sections, that the Acœla has a nervous system, almost simultaneously discovered by Metchnikoff, herself, and Delage, and demonstrates that it possesses also a pharynx and a digestive cavity; that its teguments are histologically differentiated, and that the name Acæla is not applicable to adult individuals, so that she has felt bound to change this name into *Pseudo-acoela*. This very elaborate monograph being published in French, it is accessible to all men of science. It is illustrated with sixteen well-printed plates, lithographed in Warsaw, from the author's own drawings.

IT is known that certain plant-stuffs (alkaloids, tannin, oxalic acid, &c.) protect plants from attack by animals. This function, in the case of oxalic acid, has been recently studied by Herr Giessler (*Jenaische Zeits.*), taking species of rumex, oxalis, and begonia. The acid mostly occurs in the epidermis and peripheral tissues of the vegetative organs; parts underground have little or none. The leaves show most, but the acid may be found in the stem, and the leaf and flower stalks. Curiously, it does not, like other protective matters, appear in young organs. The older and more sappy the tissues, the more oxalic acid do they contain. Snails, which avoided those plants in the natural state, ate them when the oxalic acid had been precipitated. The substitution of various means of protection for one another was elucidated by Stahl; plants not protected mechanically have chemical protection, and *vice versâ*. In the plants studied by Herr Giessler mechanical protection is deficient. Further, in organs that have little or no oxalic acid, is found tannin. These two "vicariate" with each other also in different species of a genus. In many tissues both occur together. The protective function of a secretion, lastly, does not exclude other functions. Thus, regarding the epidermis as a water-reservoir, the osmotically very active organic acids doubtless play an important part in the filling of the cells with water. The occurrence of begonia and oxalis species in very dry places, as also the deficiency in means of protection against transpiration, more pronounced the higher the quantity of acid, put this function of oxalic acid in a still clearer light.

PROF. SOLLAS, F.R.S., communicated a paper on the granophyre of the Carlingford and Morne mountains to a recent meeting of the Royal Irish Academy. The granophyre is everywhere intrusive into the gabbro, and owing to the contrasted character of the two rocks it is possible to trace out their relation in the fullest manner. The behaviour of the granophyre is of great interest; from wide dykes, comparatively few in number, it passes into innumerable thin lamellar injections, which seam the gabbro through and through. These can be further followed into cracks of microscopic minuteness, and these swell out at intervals into ganglia, which give a white spotted appearance to the otherwise almost black gabbro. The ganglia are granophyric infillings of what were once drusy cavities in the gabbro, and it is suggested that the quartz so frequently found in gabbro associated with granitic rocks, as *e.g.*, at Carrock Fell, is of a similar origin. Of equal interest is the abundance of gabbro fragments included in the granophyre, and since the mineral constituents of the gabbro present features peculiarly easy to recognise, there is no difficulty in following the changes which they have suffered in consequence of their immersion in the originally molten granophyre. Thus the Bytownite, which frequently occurs as phenocrysts in the granophyre, has frequently become surrounded by a marginal zone of orthoclase, and the diallage can be traced into amphibole and biotite and colourless granules of pyroxene, which either remain in clusters about their place of birth or are dispersed throughout the rock. It would, indeed, appear that the ferro-magnesian constituents of the granophyre which have led observers to designate it as syenite and augite granophyre are entirely derived from the grabbro, and it hence becomes an interesting question to consider whether in numerous other instances rocks intermediate in composition to the extremely acid and basic rocks with which they are associated may not also have arisen from the admixture of two already differentiated magmas, and not by the progressive modification of a single original magma.

AT a recent exhibition by the French Société de Physique, MM. Macé de Lépinay and Perot showed a lecture-experiment illustrating well the phenomenon of mirage. A long vessel with plane sides contains a saline solution, on which is poured some distilled water. By diffusion, the liquids gradually mix and form a layer in which the density varies in a continuous way. If now a ray be sent, by means of a reflector, slightly upwards in the axis of the vessel, it describes a curve, passing through a maximum and descending. Its trace on a vertical plate of ground glass traversing the tube throughout its length, shows exactly the path taken, and gives a very pretty effect. On the same occasion, M. Pellin exhibited photographs of the fine gratings produced by Prof. Rowland, of Baltimore, whereby fine lecture experiments in diffraction can be produced at but small cost.

AN elegant method of optically studying the process of diffusion in liquids is described by Herr O. Wiener in *Wiedemann's Annalen*. It is somewhat similar to MM. de Lépinay and Perot's beautiful imitation of the mirage, and consists in sending a beam of parallel rays through a vessel containing two liquids of different density and refractive power. A trace of fluorescein makes the path of the rays visible, and shows that they are bent away from the less highly refracting liquid in the region where diffusion is taking place. By carefully pouring a layer of carbon bisulphide on to one of chloroform, and a layer of alcohol on the top of both, it is possible to make the beam describe a wavy path, due to alternate refractions by the alcohol and the chloroform, both of which are less highly refractive than carbon bisulphide. For the purpose of minutely investigating the process another arrangement is adopted. Parallel rays of monochromatic light are sent through a slit at 45 degrees to the horizon, and pass through the diffusion vessel on to a screen. The dividing surface is indicated by a decided upward or downward bend of the line on the screen, which becomes gradually less pronounced and more evenly distributed as diffusion equalises the refractive indices. The amount of vertical displacement at each point of the curve measures the difference of concentration in the region traversed by the ray. The constant of diffusion can be calculated from the rate of change of the diffusion curve, and the displacement of the point of maximum bending indicates the lesser diffusivity of the liquid towards which it takes place. Herr Wiener has also successfully applied the method to the determination of the thermal conductivity of water by photographing the diffusion curve in various stages.

The question as to whether there is a true hysteresis in the case of dielectrics has received considerable attention lately, and Arno, Hess, and Janet have published the results of extensive researches on this subject. A note by M. Charles Borel in the current number of the *Comptes Rendus* has some bearing on this point. He suspends a disc of paraffined paper by its centre in front of a plate which is charged, by means of a rotating commutator, alternately positively and negatively. The duration of the charge was 0·006 second, and between charges of opposite sign it was put to earth for an equal intervals When a glass rod is placed on one side of the disc, so that the plane of the disc and the axis of the rod are parallel to the lines of force of the field, and the end of the rod nearest the charged plate is slightly inclined towards the disc, the latter is rotated. This rotation can be explained by the mutual action of the residual charges in the disc and glass rod when the charged plate is earthed. Different specimens of glass produced very different results on the suspended disc, some having no effect whatever. The replacement of the disc of paraffined paper by one of mica had little effect, while discs of pure paraffin or ebonite showed only a feeble effect. It was found that rods formed of conductors or of good insulators, such as ebonite and shellac, produced a feeble rotation in the opposite direction to that produced by most dielectrics. If the rotation is really due to the residual electrification of the disc or rod this rotation in the inverse direction may be expected whenever the rod has no residual electrification. The effects of crystals held in different directions was tried, and it was found that, in general, the deflection varied with the direction of the crystal, which was normal to the charging plate.

Wiedemann's Annalen for May contains a paper by Herr J. von Geitler on the reflexion of electrical waves in wires. The waves were generated by means of the arrangement used by Blondlot, the secondary circuit being connected to two parallel wires 280 metres long. The variation of potential along these wires was measured by means of a differential electrometer, consisting of a double aluminium needle suspended by a quartz fibre before four metallic plates. These plates were connected, two and two, to the parts of the wire whose difference of potential had to be measured, in such a way that the attraction between the pairs of plates tended to turn the needle in opposite directions. The experiments show that if a series of electrical waves travel along two equal and uniform parallel wires there is a regular loss of phase and partial refexion wherever the parallelism of the wires is destroyed, or wherever there is a change in the diameter of the wire. The same effect is produced by joining the plates of a condenser to the two wires at any point. The curves showing the connection between the electrometer throw and the length of a branch circuit attached to the main wires are of a very curious form, and owing to the loss of half a wave length at the reflexion at the end of the branch circuit in one case, the curve obtained when the ends were separate was the exact inverse of that obtained when the ends were joined together.

Mr. W. Roe contributes to the *Agricultural Journal*, of Cape Colony (April 6) an interesting paper on some of the disadvantages that may result from irrigation. Most water used for irrigation contains variable quantities of soluble salts, more especially soda salts, chlorides, and sulphates, not taken up largely by plants. Every application of water, therefore, adds to the saline ingredients of the soil—a very different effect from that of excess of rain water, which so far as there is open subsoil for it to drain away would be likely to take out rather than add to the soluble salines in the soil. This mischief, accumulation of salts in the soil, is aggravated in a dry-air land where evaporation is great. The air, acting like a sponge on a surface, takes up the water, leaving the accumulated salts in the surface soil. But this surface soil is as the sponge to the layer beneath. Constantly after each water-leading the water is drawn to the surface, and evaporated, and its measure of salts left behind. Obviously the harm done by this accumulated salt will depend on the nature and quantity of the salines in the water used, as also upon the quantity of water applied. A good quality of river water may vary in having five to twelve grains to the gallon of soluble salts ; more than this becomes risky, unless the sub-soil is very porous.

The Rugby School Natural History Society has issued its report for the year 1892. The report, as the editor explains, differs from those of previous years in that the papers included in it deal solely with the natural history of the neighbourhood. They are all, with one exception, reprinted from the Rev. W. O. Wait's "Rugby, Past and Present," and as in the main they are written by old members of the Society, they may be regarded as presenting a kind of summary of the Society's work from its foundation to the present day.

A paper on the Siyin Chins, by Major F. M. Rundall, is included in the third volume of the "Supplementary Papers" of the Royal Geographical Society, and has also been printed separately. The author knows the Chin Hills well, and gives a very interesting account both of them and of the tribes by which they are inhabited. The paper is accompanied by a map.

The new instalment of the proceedings of the Geologists' Association includes the presidential address of Prof. J. F. Blake, delivered on February 3. It deals with the basis of the classification of Ammonites.

An essay on the laws of heredity, read originally by S. S. Buckman before the Cotteswold Field Club, has been translated into German, and issued as one of the series of "Darwinistische Schriften," published by Ernst Günther, of Leipzig. The German title of Mr. Buckman's work is "Vererbungsgesetze und ihre Anwendung auf den Menschen."

Messrs. Crosby, Lockwood and Son will issue in a few days an English edition of the "Handbook of the Steam Engine," by Herm. Haeder. The editor and translator of the English edition is Mr. H. H. P. Powles.

"A Contribution to the Chemistry and Physiology of Foliage Leaves," by H. T. Brown, F.R.S., and Dr. G. H. Morris, has been reprinted, by Messrs. Harrison and Sons, from the "Journal of the Chemical Society," May, 1893.

The Entomological Society of London has issued a catalogue of its library. The work has been edited by G. C. Champion, hon. librarian, assisted by R. McLachlan, F.R.S., and D. Sharp, F.R.S. Great additions to the collection have been made since the last printed catalogue was published in 1861 ; but there are still certain deficiencies, and Mr. Champion expresses a hope that some of these may be speedily supplied by Fellows, and that the publication of a separate Appendix may thus at no distant date be rendered necessary.

A COMPREHENSIVE study of the nature of the dissociation of hydriodic acid gas by heat, the conditions of equilibrium of the dissociated constituents, and the circumstances under which recombination occurs, has been made by Prof. Victor Meyer and Herr Bodenstein, and their results are contributed to the current number of the *Berichte*. The investigation was conducted upon similar lines to Prof. Meyer's recent experiments upon gaseous mixtures of hydrogen and oxygen, a series of a large number of equal-sized bulbs connected by capillary tubes being simultaneously filled with the pure gas and subsequently sealed and separated by fusion of the capillaries. In commencing the experiments Prof. Meyer was surprised to observe the comparative readiness with which gaseous iodine and hydrogen unite without the aid of platinum sponge or other condensing agents. If a glass tube containing a little iodine is filled with hydrogen, sealed, heated in a bath of the vapour of boiling sulphur, and after cooling opened under water, a considerable escape of pent-up hydriodic acid gas occurs, and the water immediately afterwards ascends in the tube owing to the absorption of the remainder. The hydriodic acid for the purpose of the experiments was all prepared by the direct union of the pure elements, inasmuch as the gas prepared by the usual method from iodide of phosphorus was always found to contain admixed volatile phosphorus compounds. The preparation was conducted by leading the mixture of iodine vapour and hydrogen over heated platinised asbestos, when it was found that 86 per cent. of the iodine entered into combination. The product, after passing through a suitable vessel in which the uncombined iodine was condensed, was received in cooled water, the gas regenerated by warming the fuming aqueous solution, and finally freed from moisture by leading it over phosphoric anhydride and from the last traces of free iodine by passing it over red phosphorus free from yellow phosphorus and lower oxides of phosphorus. The hydriodic acid gas thus obtained proved to contain no perceptible trace of impurity. Before proceeding to fill the bulbs the air was expelled from them by means of a current of pure hydrogen, which was allowed to pass through them for 24 hours, with occasional heating to near the softening point of the glass in order to remove the film of condensed air adhering to the surface of the glass. The hydrogen was finally displaced by pure hydriodic acid and the bulbs sealed. These extreme precautions, which were adopted in order to secure a number of specimens of pure hydriodic acid, afford a striking example of the infinite pains which are required to effect the final settlement of many of the apparently simple problems of elementary chemistry.

PROF. MEYER has definitely decided the question of the action of light upon pure hydriodic acid gas. Bulbs exposed upon the roof of the Heidelberg laboratory during the summer months became filled in a few days with large brilliant crystals of iodine. After ten days' exposure 58 per cent. of the gas had been dissociated, and at the end of the summer 99 per cent., or practically all. The fact that the waves of light are so active in effecting dissociation rendered it imperative that the thermal experiments should be conducted in the dark. The whole of the above experiments in connection with the preparation of the gas and the filling of the bulbs were therefore conducted in a dark room. The thermal results may be very briefly summarised. The statement in text-books that hydriodic acid commences to dissociate at 180° is incorrect. It is only in presence of admixed air that this occurs. At 310° the decomposition of the pure gas is so slight that it would take 2,000 hours to attain the point of maximum dissociation at which equilibrium is established. This point was determined indirectly to be attained when 0·1669 of the original quantity of gas was dissociated. At the temperature of the vapour of boiling mercury (350°) equilibrium was found directly to be established when 0·1731 was decomposed. At 394° (boiling retene) 0·1957 was dissociated, and at the temperature (448°) of boiling sulphur 0·2150. It is of particular interest to learn that Prof. Meyer has further proved by direct experiment that the formation of hydriodic acid from gaseous hydrogen and iodine proceeds at any temperature until exactly the same condition of equilibrium is attained as in the corresponding dissociation experiment. Thus when the synthesis of hydriodic acid was conducted at the temperature of sulphur vapour the reaction proceeded until only 0·21 of the elementary gases remained uncombined, the same amount as was dissociated when starting with the compound gas. Perhaps the most interesting result of the investigation is that concerning the rapidity of the dissociation. It has been found that whenever two bulbs of equal size are heated for equal lengths of time precisely the same amount of decomposition or of formation occurs. The reaction is thus found to proceed with strict regularity, the amount of dissociation or of synthesis at any fixed temperature being a direct function of the time, and capable of expression by a simple mathematical formula which is given in the memoir and which is amply verified by a large number of experiments.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include the Mollusca *Eulima distorta* and *Rostanga coccinea*, the Isopoda *Anthura gracilis* and *Munna Kröyeri*, and the Brachyura *Eurynome aspera* and *Portunus marmoreus*. The gelatinous alga, which has been so abundant in the townettings since the beginning of April, has at length almost completely disappeared. Swarms of the Leptomedusæ *Irene pellucida* (half-grown) and *Obelia lucifera* (full-grown and mature) have repeatedly been taken; but for some weeks past an occasional specimen of *Corymorpha nutans* has been the only representative of the Anthomedusæ. A single large *Bipinnaria* larva has been observed. On the shore young individuals of this year's growth of the Nemertines *Amphiporus lactifloreus* and *Lineus obscurus* (= *gesserensis*), and of the Crustacean *Carcinus mænas* are now plentiful. The following animals are now breeding:—Several *Terebellidæ*, the Opisthobranch *Philine aperta*; the Crustacea *Virbius varians*, *Portunus marmoreus*, *Stenorhynchus phalangium* and *tenuirostris*.

THE additions to the Zoological Society's Gardens during the past week include a Common Hedgehog (*Erinaceus europæus*, white var.) from Berkshire, presented by Mr. R. T. Hermon-Hodge: a Ruddy Ichneumon (*Herpestes smithi*) from India, presented by Mr. Maurice Welsh; a Guillemot (*Lomvia troile*) British, presented by Mr. H. B. Hewetson, F.Z.S.; two Ringhals Snakes (*Sepedon hæmachetes*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; an Aurora Snake (*Lamprophis aurora*) from South Africa, presented by Mr. T. E. Goodall; a Levaillant's Amazon (*Chrysotis levaillanti*) from Mexico, a Grey Parrot (*Psittacus erithacus*) from West Africa, a Cardinal Grosbeak (*Cardinalis virginianus*), a Rose-breasted Grosbeak (*Hedymeles ludovicianus*) from North America, deposited; a Jaguar (*Felis onca*, ♀) from South America, two Striped Hyænas (*Hynna striata*, ♂ ♀) from North Africa, a Black-necked Swan (*Cygnus nigricollis*, ♂) from Antarctic America, twelve Green Lizards (*Lacerta viridis*) South European, purchased.

OUR ASTRONOMICAL COLUMN.

THE ECLIPSE OF APRIL, 1893.—M. Bigourdan communicates to *Comptes Rendus* for May 23 (No. 21) a brief preliminary account of his observations made during this total eclipse of the sun. The station he occupied was Joal (approximately Longitude 1h. 16m. 38s. E. of Paris, and Latitude 14° 9′ 25″ N.)

and the observations were made from the Observatory erected by the Expedition of the Bureau des Longitudes. With an eyepiece magnifying 190 times he observed several occultations of solar spots by the moon, and in about fifteen cases he noticed the phenomenon that is equivalent to that seen in observations of the Transit of Venus and known as the black drop. It was produced, he says, not only at the contact of large spots, but at the point of contact of small ones, and even of the simple filaments forming the penumbræ of spots. M. Bigourdan also made a special look for the phenomena known as Baily's beads, sometimes seen when the sun has been reduced to a very fine crescent by the advance of the lunar disc, but from all accounts he seems to have been unable to see any trace of them. A search round the sun for an intra-Mercurial planet, with a telescope giving a field of 25′, was also made, but with no satisfactory result, since he says that his instrument was not suited for that purpose: the negative result thus obtained affords no argument against the existence of such a body. The duration of totality lasted exactly 4m. 1s.

FINLAY'S COMET (1886, VII.).—The following is the current ephemeris of this periodic comet, as given in *Astronomische Nachrichten*, No. 3164:—

12h. M.T. Paris.

AURORA OBSERVATIONS.—In the event of Lieut. Peary's expedition to a high station in North Greenland (about Lat. 77° 30′ N. and Long. 70° 15′ W.), where regular observations of the aurora will be undertaken, it is hoped that everyone, wherever he may be, will help to supplement these observations by noting himself the times of absence and presence of this phenomenon. With so many workers in so many lands, it is needless to say that a systematic method of recording what is seen should be followed. With the intention of supplying this demand, Mr. M. A. Veeder has issued a set of blanks similar to those that will be used in the expedition, so that when properly filled up comparisons can be made in detail. In addition to the investigation of the local distribution of the aurora, it is hoped that the electro-magnetic conditions of solar origin may be more inquired into, and it is on this account that these circulars have been sent to both solar and magnetical observatories as well as to individual observers. As for the Arctic records, they will be continuous whenever observation is possible, relays of observers connected with the expedition relieving each other. In making such observations it is emphasised here that minute descriptions of the formation of arches, streamers, prismatic colours, and the like, accompanying such variations in the extent of displays, are of interest, but are far less important than that the times should be noted as accurately as possible. Any one desiring these blanks can be supplied directly by applying to M. A. Veeder, New York.

THE CONSTANT OF ABERRATION.—Prof. Chandler, in the *Astronomical Journal* (No. 296), gives the third of his most important papers relating to the constant of aberration, treating in this article specially of Struve's Prime-Vertical Observations, 1840–55, from the new point of view with respect to the variation of latitude. In this discussion, in addition to a direct solution for all the unknowns, he has made an indeterminate one, employing the constants pertaining to the 427-day term, and expressing the unknowns in terms of y and z. As regards the former solution, employing the observations of the seven stars from the years 1840–42, the value of the observations obtained is 20″·533, Struve's value from the same material being 20″·445, and for the whole data from 1840–55 the aberration is 20″·514. This last-mentioned value would be the "definite value from Struve's Prime-Vertical Observations, if we accept the direct solution as the best," but he says the *indeterminate* solution throws doubt upon this point. The definite value, as given by this solution, gives $20''\cdot481 + 0\cdot111y + 0\cdot230z$; and, since as yet the most probable values of these constants are not known, those of the 427-day period applied to the special case of Polaris, which were independent of the aberration, give, on this assumption, 20″·474, a value, as will be noticed, smaller than that by the direct solution. The value 20″·500 for the aberration constant is, according to Prof. Chandler, too great, as inferred from the discussion here given. As a "matter of interest" he gives the values of the aberrations deduced from the observations of the several stars made in 1840–42.

THE ASTRONOMICAL DAY.—"Is it desirable, all interests considered, that on and after January 1, 1901, the astronomical day should everywhere begin at mean midnight?" This is the question that has been put forward by a joint committee of the Canadian Institute and the Astronomical and Physical Society of Toronto, and printed in a circular-letter addressed to astronomers of all nations. Many of our readers may remember that as far back as 1884 the Washington International Conference carried unanimously the following resolution, there being representatives of twenty-five nations, "counting among them several astronomers of world-wide fame," that "the conference expresses the hope that as soon as may be practicable, the astronomical and nautical days will be arranged everywhere to begin at mean midnight." That the astronomical and civil day should start together at the same moment seems without doubt the right method of procedure, for what is gained really by reckoning the astronomical time from noon and the civil from the preceding midnight? It is true that changes will have to be made in the *Nautical Almanac*, and all such-like year-books, both astronomical and nautical; but on the assumption that the change is made simultaneously by all nations, and taking into account that such a change cannot come into vogue for five or six years on account of the fact that these books are printed a few years in advance, there seems really no difficulty ahead. The suggestion that the change, if made, should take place with the change of the century seems to be an excellent epoch for such a transition, for besides giving time for a thorough discussion of so important a question, it will, as Otto Struve says, "stamp itself on the memory of all who hereafter would be busied in the investigations in which exact chronology plays a part."

ROYAL OBSERVATORY, GREENWICH.—The Annual Visitation of the Royal Observatory at Greenwich by the Board of Visitors takes place on Saturday, June 3 next. The Observatory will be open for inspection at 3 p.m.

GEOGRAPHICAL NOTES.

DR. NANSEN writes confirming the statement made in this column as to the baselessness of the assertions regarding the failure of his expedition. He is making rapid progress with his preparations, and expects to sail in the *Fram* on his great venture on June 20.

THE most recent change of name in Africa is the adoption of the official title Niger Coast Protectorate for what was previously known as the Oil Rivers Protectorate, comprising the coastward part of the Niger delta.

NATAL, which has been a British colony for fifty years, has entered upon the final stage of colonial independence by the adoption of responsible government. It is expected that this step will lead to a rapid development of the resources of the country, and a considerable extension of its railways.

THE Antarctic whaler *Balæna* put into Portland Roads for coal on May 25, and reached Dundee on May 30, being the first to return. Mr. W. S. Bruce, who was on board as surgeon and in charge of scientific observations, reports that the homeward trip was favoured by very fine weather. He confirms our fear that opportunities for scientific work had often to be lost on account of the purely commercial character of the trip, and the rigid interpretation of his instructions by the captain. An account of the voyage and its results will probably be given to the meeting of the British Association at Nottingham. On the return journey a series of floats was thrown overboard from the Antarctic ice-margin to the equator, in order to endeavour to get light on the direction and speed of the currents. The lowest air temperature experienced amongst the ice was 21° F.

THE new number of the *Geographical Journal* publishes an old minute of a committee of the Royal Geographical Society held in 1845 to consider the nomenclature of the oceans. At this meeting Sir John Franklin took part, and as he sailed on his last voyage shortly afterwards it is possible that his absence prevented the matter from being further discussed. The provisional resolution come to by the committee was to give the following names and limits to the oceans:—Arctic Ocean and Antarctic Ocean, to the waters lying within the Arctic and Antarctic Circles respectively. The Atlantic and Pacific Oceans stretched from the Arctic to the Antarctic Circles, and were separated from each other by the meridian of Cape Horn. The Indian Ocean extended from India to the Antarctic Circle, divided from the Atlantic by the meridian of Cape Agulhas and from the Pacific by that of the south point of Tasmania. Mr. Arrowsmith, the eminent cartographer, was present at the meeting, and it is customary in Continental works to refer this systematic definition of the oceans to him. As a matter of fact his maps had a great deal to do with the nomenclature acquiring popularity. The committee proposed a triple sub-division of the Atlantic and Pacific into a northern, southern, and inter-tropical part. This has not come into general use. It is time that the question of oceanic nomenclature should be seriously considered again, and that the morphology and physiology of these great features be taken into account as well as their superficial outlines in determining a scientific classification.

THE IRON AND STEEL INSTITUTE.

A MEETING of the Iron and Steel Institute was held on Wednesday and Thursday of last week, May 24 and 25. There was a somewhat short programme, only five papers being on the agenda, and one of these was not read. There were, however, two additional papers afterwards brought in, but they were only read by title, and as they were not discussed, had very little influence on the proceedings. The papers read were as follows:—On the elimination of sulphur from iron and steel, by J. E. Stead, of Middlesbrough; on the Saniter process of desulphurisation, by E. H. Saniter, Wigan; notes on puddling iron, by John Head; on the recording pyrometer, by Prof. W. H. Roberts Austen. On the members assembling on Wednesday morning, the president, Sir Frederick Abel, occupied the chair, and the usual formal business of reading the minutes was first undertaken, after which the report of the council was read by the secretary, from which it appears that the advance of the institute in respect to membership has not been altogether satisfactory of late. The resignation of the secretary, Mr. Jeans, was also mentioned. The opportunity has been taken by the council, of Mr. Jeans's retirement, to introduce some modifications in the secretarial and editorial arrangements. Mr. Bennett H. Brough, an Associate of the Royal School of Mines, who has for some time past been an assistant professor at the Royal College of Science, has been appointed to the office of secretary and editor to the institute.

Sir Frederick Abel next evacuated the presidential chair, which was then occupied by Mr. E. Windsor Richards, the new president. Mr. Richards is an excellent representative of the practical steel manufacturer, having been engaged in the iron and steel trades all his life. He was for some time manager at the important steel works at Eston in Middlesborough. Some time ago he vacated his position there to take the management of the Lowmoor Iron Works, an establishment almost classical in its antiquity, in an industry which has been so entirely reformed within the last few years. Lowmoor, however, keeps to its old traditions and still produces best Yorkshire iron in the manner practised from a period extending back into the early days of iron manufacture, and this in spite of the improvements and advances made in the manufacture of mild steel. Mr. Richards having been conducted to the chair, at once proceeded to deliver his inaugural address. One of the most important parts was his reference to the remarkable extent to which English steel is made from foreign ore. It is, of course, unnecessary to state at any length the reason for this, as the fact must be well known to nearly all our readers. The iron ores of Britain, upon which our engineering supremacy was so long supposed to rest, is, with some not very important exceptions, unfitted for the production of ingot iron, more generally known as Bessemer, or mild steel. The chief reason for this is the considerable percentage of phosphorus it contains. We have, however, in Lancashire and Cumberland, hæmatite ores which are of a suitable description, but these are not so largely worked as at first might be thought they would be, and the bulk of hæmatite ore required for steel making in England is brought from Bilbao, in North Spain. It has been generally thought of late that these deposits are being rapidly exhausted, and though the use of calcium will perhaps somewhat extend the life of the supply, the end may be sufficiently near to the present time to make it worthy of the serious consideration of steel makers. In the basic process, there is, however, a means by which our native phosphoric ores can be rendered suitable, to a large extent, for steel making purposes, and the successful working of the basic system is therefore a matter of national concern. In England, the process has received serious opposition. Perhaps we have been over-conservative in this matter; or perhaps, on the other hand, we have displayed no more than salutary caution. However this may be, the Germans have gone far ahead of us in the production of basic steel. Germany, like England, has large deposits of phosphoric ore and, unlike England, has not that free sea communication with Spain, which has rendered the importation of hæmatite ores a matter of little difficulty and small expense. It was natural, therefore, that Germany should take hold of the new system with less caution and more vigour than the English steel makers, but the result has been somewhat antagonistic to English interests. Mr. Windsor Richards, in his presidential address, told us that the west coast of England has raised 2¾ million tons of ore, free from phosphorus, and could probably increase that quantity to produce 1½ million tons of pig iron, should the demand arise. During the twelve months ending December 1892, the quantity of basic steel made in England was 406,839 tons. In Germany and Luxemburg 2,013,484 tons of steel were made from phosphoric ores.

Mr. Windsor Richards is now, as we have said, an "ironman," which seems a curious thing in the present day, after he has held, perhaps the most important position of his time in the steel trade; however, there is yet a large demand for Lowmoor iron, and the old-fashioned methods of production are still in vogue. Of this he gave some very interesting particulars. The address dealt at some length with the question of over-production, and it seems pretty evident that our facilities for making steel are far ahead of the demand for the material. In spite of this money is still being expended in steel-making plant, although so large a part of that already existing is at present lying idle, and appears likely to do so. The year 1892 was in many respects one of the very worst the iron and steel industry has ever known.

The two papers by Mr. Stead and Mr. Saniter on the elimination of sulphur from iron, were contributions of great value. The subject is one of very considerable importance, and fortunately has been occupying the attention of metallurgists for some time past. It would be impossible for us, in a brief notice of this kind, to give an abstract of these two papers; indeed they are only complementary to papers already read by the authors at former meetings. Calcium chloride is the purifying material in admixture with lime, and the process is adapted, either for purifying fluid iron or pig iron direct from the blast furnace. The process is effected by running the fluid metal into a ladle having a layer of the purifying materials on the bottom, and afterwards running the metal into pigs or plate metal for subsequent use in the puddling process; or the crude sulphury pig may be treated in the basic Siemens furnace or Bessemer converter, with the desulphurising mixture. About ½ cwt. of crude calcium chloride is used per ton of steel, in conjunction with an excess of lime above that which is usually employed; the cost of the calcium chloride is about 35*s.* per ton. About 70 per cent of sulphur can be removed from the charge of metal in an open hearth furnace by this process. It may be added that the process is in practical working at Wigan. What we have already said with regard to dephosphorisation of ore in its bearing on the use of our native ores also applies, to a great extent, to desulphurisation, and although Mr. Saniter does not stand alone in the introduction of a desulphurising process, there is no doubt that he has rendered this country considerable service by his efforts in this direction. The reading of these two papers, together with the introductory business and the presidential address, occupied the whole of the Wednesday sitting, and the discussion on both papers was taken jointly on Thursday morning. The chief point raised was whether the process was one requiring such delicacy in manipulation that ordinary workmen could not be trusted to carry it out so as to produce uniform results. Whether this objection will be fatal time will show, but the general opinion appeared to be that by employing fairly skilled workmen the difficulties of manipulation were not such as could not be got over, and that fairly uniform results would follow reasonable care in working.

The next business was the reading of Prof. Roberts-Austen's paper on the recording pyrometer. It will be remembered that at the annual meeting of two years ago, Prof. Roberts Austen gave a description of the Le Chatelier pyrometer, and the application of it, which he had introduced, by which it was adapted for recording work in blast furnace practice. The object of the present paper was to give some particulars of the most recent form of this recording pyrometer, which Prof. Roberts-Austen has devised. At the request of Mr. E. P. Martin, Managing Director of the Dowlais Iron Works, Cardiff, an instrument was made and put into operation as a means of recording temperature of the blast in an iron smelting furnace. The spot of light from the mirror of a galvonometer is thrown on sensitised paper, the paper itself being traversed at a uniform speed. In this way the record of temperature at all times is obtained. The author gave an instance of the value of the instrument. The blast to the furnace in question was supplied by a number of hot blast stoves on the ordinary regenerative principle. When the chequer work in a stove has been heated up sufficiently and the blast is first turned on for supply of the furnace, the temperature of the blast is naturally at its maximum. As the blast cools the chequer work, by abstracting heat from it, the temperature gradually falls, and it continues to decrease until it is considered desirable to re-heat the stove, and then a new stove is switched on. It will be seen therefore, that the temperature of the blast in the main, common to two or more stoves, will vary regularly, so that a curve on the diagram indicating temperature, will consist of a number of more or less steep inclinations; in fact, very much representing the teeth of a saw. That would be the normal inclination; occasionally, however, the gas valves leak, and then the stove may be receiving hot gases when it ought only to be passing air. The average temperature when this leaky stove is in use will naturally be higher than that due to another stove; in fact, it will be heated at the expense of the remaining number of the group. The result is antagonistic to regular working which is so much desired in blast furnace practice, and though the evil effect may be neutralised by the heat absorbing property of the large mass of material in the blast furnace—acting, as it were, as a fly-wheel for heat—the state of irregularity, if carried to excess, might be very harmful. It is also, of course, desirable that the blast furnace operator should know at the earliest time when his valves are going wrong; in fact, the whole system upon which the Cowper stove is based bears on the proper reversal of the blast. Prof. Robert Austen's apparatus fulfils the required conditions in supplying the knowledge required, and the invention cannot fail to be one of the greatest service to the metallurgist.

A paper by Mr. John Head on puddling iron was next read and was followed by a short discussion, after which the meeting concluded with the usual votes of thanks.

ROYAL GEOGRAPHICAL SOCIETY ANNIVERSARY MEETING.

THE anniversary meeting of the Royal Geographical Society held on Monday afternoon was, as we anticipated, exceptionally large and representative. The report of the council stated that the membership of the Society on the 1st of May was 3691 (including 22 ladies), a net increase of 166 fellows since May 1st, 1892, being the largest net addition to the membership of the Society since 1875. The total net income for the year was £93,000, and the expenditure £9012. In addition to the services performed to the fellows and the public by means of evening meetings, the use of the Map Room and Library and the publication of the *Geographical Journal*, twenty four intending travellers have received instruction in practical astronomy and route-surveying from Mr. Coles, and instruments have been lent to eleven travellers for use in all parts of the world.

In order to express disapproval of the words we italicise in the first paragraph of the report, which ran as follows:—

Membership.—The question of electing Ladies as Ordinary Fellows was considered by a Special General Meeting on April 24th, when it was decided in the negative by a considerable majority. The Council regard this vote (unless hereafter rescinded by a General Meeting) as conclusive against any further election of Ladies as Ordinary Fellows, *without prejudice to the* status *of those already elected.* They consider that, under the circumstances, all the legal expenses incurred in connection with this important question may equitably be defrayed by the Society, and they have accordingly provided for their being so defrayed.

Mr. Dibden, seconded by Colonel Montague, moved the rejection of the report, but on a division being taken the report was accepted by a large majority. The medals and other awards for the year were then presented as follows:—

The Founder's Medal, to Frederick Courtney Selous, in recognition of his extensive explorations and surveys in British South Africa. The Patron's Medal, to W. Woodville Rockhill, for his travels and explorations in Western China, Kokonor, Tsaidam and N.E. Tibet. The Murchison Grant for 1893, to Mr. R. W. Senior, who, for several years in succession, has carried out a most laborious duty in the higher ranges of Kulu and Lahaul, Punjab Himalayas, and the results achieved in point of accuracy, expedition, and amount of work done, have been exceptional in the face of great hardships and great physical difficulties. The Gill Memorial, to Mr. Henry O. Forbes, for his explorations and natural history observations in New Guinea, the Malay Archipelago, and the Chatham Islands. The Cuthbert Peek Grant, to Mr. Charles Hose, for explorations and natural history observations and collections in Sarâwak, North Borneo. Six prizes of £5 each, and eight of books, given by the Royal Geographical Society to Students in Training Colleges for 1893, were presented to the successful candidates who were introduced by Mr. Mackinder.

A ballot was then taken for the election of officers and council for the ensuing year, and the list proposed by the council was, as usual, adopted. The new president is Mr. Clements R. Markham, F.R.S., and the vice-presidents are the Hon. G. C. Brodrick, Sir Joseph Hooker, F.R.S., Sir John Kirk, F.R.S., Dr. W. T. Blanford, F.R.S., General R. Strachey, F.R.S., and Captain W. J. L. Wharton, F.R.S.

Sir M. E. Grant Duff, the retiring president, then read the anniversary address on the progress of geography, in which he summarised the various activities of the Society. In the course of this he said that during the four years in which he had the honour to be president, he had seen the number of Fellows increase by three hundred and fifty-eight, and they were now close upon three thousand seven hundred. Before long the Society would have to take into the most serious consideration the acquisition of a new domicile. "Our constantly increasing collections would of themselves, as I have pointed out before, ere long drive us from our present quarters, and we have, in addition, reason to believe that even if we could extend our borders where we now are, on anything like reasonable terms, which we cannot, certain changes in the streets in this part of the town would ere long improve us off the face of creation. Then, although the University of London has been most kind to us in lending us their theatre, and although the character of our papers and of our publications, as well as our position as the leading geographical society of the world make us, I think, not unworthy recipients of the kindness of a university, whose operations extend over the whole of the British Empire, we cannot look forward to the present state of things continuing for an indefinite period. A vote of the Senate might at any time put an end to it."

An epitome of the year's exploration—which has been sufficiently recorded in our "Geographical Notes" from week to week—concluded the address, which was received with great applause. On the motion of Lord Northbrook, seconded by Sir John Lubbock, an enthusiastic vote of thanks was passed to the retiring president, who briefly replied.

At this stage a controversy regarding the question of the admission of women to the Society was started, and after some spirited speaking, the leading opponents of the recent action of the council stated that they were perfectly prepared to concur with the wishes of a majority of the Society as ascertained by means of a *plébiscite*, or a special general meeting to be convened at an early date.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The number of entries for the Honour School of Natural Science this year is 41, which compares favourably with past years, the highest number of candidates who obtained a place in the class list in any previous year being 31 in 1891 and 1886. There are also 51 candidates for the preliminary examinations in Science. Comparing these numbers with those of the candidates in other subjects, we find Literæ Humaniores 136 candidates, History 108, Law 70, Theology 65, and Mathematics 14. Of the 41 candidates who seek Honours in Natural Science 5 offer Physics, 21 Chemistry, 13 Animal Physiology, 1 Botany, and 1 Geology. It is remarkable that there is no candidate offering Animal Morphology.

It is understood, although it is not yet officially announced, that Merton College will give a biological Fellowship in October next, the examination for which will be held at the end of September or early in October.

A meeting of the demonstrators and assistants at the Museum was held on Saturday last to discuss their position as regards the rest of the University, and it was decided to memorialise the Visitatorial Board on the subject.

CAMBRIDGE.—Prof. Foster will deliver the Rede Lecture in the Senate House on June 14 at noon. The subject of the lecture is "Weariness."

Mr. F. Darwin, Deputy Professor of Botany, announces two courses of lectures, to begin during the ensuing Long Vacation, an elementary one by Mr. Willis, of Caius College, and a more advanced course by Mr. Wager, of the Yorkshire College, Leeds.

The Special Board for Medicine have issued new schedules in Physics and Elementary Biology for the First M.B. Examination. In regard to the former a practical examination in Experimental Physics is for the first time explicitly included in the scheme.

By means of the bequest of £300 to the University by the late Mr. Henry Tyson, of Kendal, a gold medal in Mathematics and Astronomy has been founded. The award will be made on the results of the examination for Part II. of the Mathematical Tripos.

The Engineering Laboratory Syndicate have approved Mr. W. C. Marshall's plans for an engineering laboratory, and submitted them to the Senate for adoption. They propose that the most urgent needs of the Department of Mechanism shall be met by proceeding with such portions of the work as it may be possible to execute with the funds at their disposal. About £3500, in addition to the amouut already subscribed, will be required to complete the building, and a further expenditure of not less than £1000 on necessary apparatus should follow. The Syndicate trust that the development of the school may not be long delayed for want of these sums.

The Tripos Examinations Syndicate have put forward a scheme by which nearly all the Triposes will begin after the last Sunday in May, and the Honours lists will be published by the end of June. This will involve the postponement of the general admission to the B.A. degree until the first week of July, which falls in the Long Vacation. The proposal is only tentative, and it will inevitably give rise to animated discussion.

Mr. E. W. MacBride, Scholar, of St. John's College, has been nominated to occupy the University's table at the Plymouth Marine Biological Laboratory in June.

Honorary degrees are to be conferred on the Maharajah of Bhaonagar, Lord Herschell (as Chairman of the Governors of the Imperial Institute), and Lord Roberts of Kandahar and Waterford; Prof. Zupitza, the eminent philologist, and Mr. Standish Hayes O'Grady, the Celtic scholar, are to be similarly honoured.

SCIENTIFIC SERIALS.

The Quarterly Journal of Microscopical Science for April, 1893, contains:—Description of a new species of Moniligaster from India, by W. Blaxland Benham (Pl. xxxii. and iii.). The species is from the Nilgiris and is named *M. indicus.*—Note on a new species of the genus Nais, by W. Blaxland Benham (Pl. xxxiii.). The worm was found in a ditch in the neighbourhood of Oxford; it is of a dull brownish colour, about a quarter of an inch in length, and is called *N. heterochæta*, from the fact that of the normally two chætæ in the dorsal bundles one is of a "crochet" shape, the other is capilliform.—On a new organ in the Lycoridea, and on the nephridium in *Nereis diversicolor*, O. F. Muell., by E. S. Goodrich (Pl. xxxiv. and xxxv.). The new organ consists of a pair of large, highly-differentiated, ciliated patches of cœlomic epithelium, which are found in every segment, except the first and the last few. These "dorsal ciliated organs" seem to occur throughout the Lycoridea, having been found in all the genera of that family examined by the author. Some notes on the minute structure of the nephridia of the Nereids are added.—On the nephridia and body-cavity of some Decapod Crustacea, by Edgar J. Allen, (Pl. xxxvi. vii. viii.). 1. The green gland of Palæmonetes (and Palæmon) at the time of the hatching of the larva has not developed a lumen. When the larva leaves the egg the lumen commences to open and the gland consists of an end-sac and a U-shaped tube, of which the distal portion gives rise to the bladder. The bladder then enlarges greatly, growing at first inwards towards the middle ventral line, then upwards, within the œsophageal nerve-ring and anterior to the œsophagus, to the middle dorsal line, where it meets its fellow of the opposite side. The two bladders grow backwards over the stomach and beneath the dorsal sac, subsequently fusing together in the middle line to form the unpaired nephro-peritoneal sac. 2. The shell-glands are the functional excretory organs at the time of the hatching and during the latter part of the embryonal period. They open at the bases of the second maxillæ, and each consists of an end-sac and a Y-shaped renal tube, which have the typical structure of a crustacean nephridium. 3. A dorsal sac, which is completely enclosed by an epithelial lining, persists in adults of Palæmon, Palæmonetes, and Crangon. 4. At its anterior end the dorsal sac is surrounded by a mass of tissue which appears to have the power of producing blood corpuscles. 5. The dorsal sac is formed as a hollowing-out in masses of mesoderm cells, which lie on either side of the cephalic aorta. 6. The body-cavity of these Crustaceans varies in different regions: (*a*) In the anterior part of the thorax it consists of a true cœlom (the dorsal sac and nephridia) and a hæmocœle; (*b*) in the posterior part of the thorax and in the abdomen, the body cavity is entirely a hæmocœle.—Note on the cœlom and vascular system of the Mollusca and Arthropoda, by Prof. E. Ray Lankester. A reprint of an abstract of an important paper read at the 1887 meeting of the British Association, and published in these pages (vol. xxxvii. p. 498). The author adds a request for specimens of Lernanthropus to enable him to complete his researches. Five species of this genus are recorded from the Mediterranean in Carus' "Prodomus Faunae Mediterraneæ."—Contributions to a knowledge of British marine Turbellaria, by F. W. Gamble (Pl. xxxix.-xli.), records 71 species, of which 28 are now added to the British fauna. Plate xxxix. contains coloured figures of ten species.—Peculiarities in the segmentation of certain Polychætes, by Florence Buchanan (Pl. xlii.).—Review of Bolsius' researches on the nephridia of Leeches by A. G. Bourne.

In the notice of the January number of the *Q.J.M.S.* the too brief account of Mr. Arthur Willy's paper on the Protochordata is we regret deemed calculated to produce a mistaken impression; it should read "that the author in consequence of new observations on the Ascidians, found it necessary to repudiate the theory of van Beneden and Julin, as to the pre-chordal vesicle of Ascidians and Amphioxus, which he had previously, without having made personal observations on the Ascidians, provisionally adopted."

THE number of the *Nuovo Giornale Botanico Italiano* for April contains three papers:—Sig. S. Sommier gives the results of a botanical tour in the region of the Lower Obi, in Siberia, including lists of the flowering plants, Vascular Cryptogams, Muscineæ, Lichens, Fungi, and Algæ obtained. A new species of fungus is described, *Helotium Sommierianum*, parasitic on *Lycopodium clavatum*. Dr. N. C. Kindberg contributes a list of mosses gathered in Southern Switzerland and Italy. Dr. E. Baroni gives measurements of the pollen-grains of various species of *Papaver*, *Chelidonium*, and *Eschscholtzia*.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 4.—"On the Thickness and Electrical Resistance of Thin Liquid Films." By A. W. Reinold, M.A., F.R.S., Professor of Physics in the Royal Naval College, Greenwich, and A. W. Rücker, M.A., F.R.S., Professor of Physics in the Royal College of Science, London.

The paper gives an account of experiments made for the purpose of determining the thickness of black soap films formed of solutions of varying composition. Two methods of experiment were employed: (1) an optical method, in which the mean thickness of about 50 plane black films contained in a tube was deduced from observations of interference phenomena; and (2) an electrical method, in which the thickness of a cylindrical black film was derived from a measurement of its electrical resistance. The optical method involves the assumption that the refractive index of a thin film of liquid is the same as that of a large quantity of the same liquid.

Reasons are given for the belief that the refractive indices in question, if not identical, differ only slightly, and hence that the thickness of a film as determined by the optical method is the true thickness.

In the electrical method the assumption is made that the specific conductivity of a liquid does not alter when the liquid is drawn out into a thin film.

If the results obtained by the two methods agree, the conclusion is that the specific resistance of a film is not affected by its tenuity; if they differ widely from each other, a change in the specific conductivity of the liquid must have taken place.

The authors showed, in 1883, that for a solution of hard soap containing 3 per cent. of KNO_3, with or without the admixture of glycerine, the mean thicknesses of black films, as measured by each of the two methods, were in close agreement. For such solutions, then, the specific conductivity is the same whether the liquid be examined in considerable bulk or in the form of a film $12\mu\mu$ in thickness. The accuracy of this result has been confirmed by a large number of observations made during the last three years.

If the proportion of KNO_3 added to the solution be diminished, the thickness of a black film, whether measured optically or electrically, is found to undergo a change.

The results obtained by the optical method show that

(1) For a given solution of hard soap the thickness of a black film increases as the percentage of KNO_3 is diminished, being $12 \cdot 4\mu\mu$ for a 3 per cent. solution, and 22·1 for a solution containing no salt. This is confirmed by experiments on soft soap.

(2) When no metallic salt is dissolved in the solution the thickness of a black film increases as the strength of the soap solution diminishes. The thicknesses are 21·6, 22·1, 27·7, and $29 \cdot 3\mu\mu$ when the proportions of soap to water are respectively 1/30, 1/40, 1/60, 1/80.

(3) If the solution contain 3 per cent. of KNO_3, variation in the proportion of soap dissolved produces very little change in the thickness of a black film.

Electrical Method.—It has been stated that for a soap solution containing 3 per cent. of KNO_3 the thickness of a black film as measured electrically is practically the same as that measured optically. If, however, the proportion of KNO_3 be diminished, the thickness (measured electrically) increased in a far larger ratio than would be inferred from the optical method. If the proportion of salt be diminished to zero, the thicknesses thus calculated are much greater than the greatest thickness at which a film can appear black. In such cases, therefore, the electrical method does not give the true thickness of the black, and the hypothesis that the specific conductivity of the film and of the liquid in mass are identical is untenable.

The following table shows the change in apparent thickness due to diminution in the quantity of dissolved salt:—

Hard Soap.

Percentage of KNO_3.	3	2	1	0·5	9
Mean apparent thickness of black film (measured electrically)	10·6 ...	12·7 ...	24·4 ...	26·5 ...	154

The large value obtained for the apparent thickness in the case of the unsalted hard soap solution is confirmed by experiments on a solution of unsalted soft soap, which gave a mean apparent thickness of $162\mu\mu$.

In different films the measured thicknesses of the black differ widely from each other, the limits being roughly $8 \cdot 3\mu\mu$ and $230\mu\mu$. This large variation is due in some cases, at all events, to a real variation in the thickness. Two different shades of black are (in cases where the solution contains little or no salt) frequently seen in a film. They are separated from each other by a line of discontinuity which is irregular in shape. Comparative measurements on the two shades of black have been made, and the results indicate that the electrical thicknesses of the two kinds of black are approximately as 2 : 1.

The results of numerous experiments carried out with the object of determining the *cause of the great increase in electrical conductivity in black films made from unsalted soap solutions* have shown that the increase of specific conductivity in question—

(1) Is independent of moderate changes of temperature.

(2) Is not due to the absorption or evaporation of water by the film.

(3) Is not due to change in the composition of the liquid by electrolytic decomposition produced by the current used to measure the electrical resistance of the film.

(4) Is not affected by a very large change in the quantity of CO_2 in the air around the film.

(5) Is practically unaltered if the films are formed in an atmosphere of oxygen.

The next question to be answered was whether the large changes in specific conductivity affect black films only, or whether similar phenomena can be detected in the case of thicker films.

The conclusions arrived at were (1) that the specific conductivity of a film increases as the thickness decreases, and (2) that this increase is less in the case of a film to which a salt has been added and is *nil* when the proportion of salt is as much as 3 per cent.

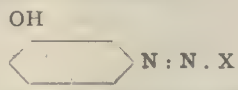
The paper concludes with a discussion as to the cause of the increase of electrical conductivity in thin films. The authors point out that it may be attributed either to a modification of the chemical constitution of the film brought about by its tenuity, or to the formation of a pellicle on the surface or to both causes combined.

Physical Society, May 12.—Prof. A. W. Rücker, F.R.S., President, in the chair.—A paper on the drawing of curves by their curvature, by C. V. Boys, F.R.S., was read, and demonstrations of the method employed given. Whilst giving a course of lectures on capillarity, in 1891, the author wished to explain the principles upon which the form of a water drop depended, and finding Lord Kelvin's rule (*Proc. R. Inst.*, Jan. 29, 1886) cumbersome, devised the modification now described. The construction depends on the fact that the total curvature is proportional to the hydrostatic pressure, *i.e.*, proportional to the depth below the plane surface of the liquid. To avoid the trouble of finding reciprocals, a rule was divided so that the distance from what would be the zero of the scale are the reciprocals of the numbers attached to them, and the curvature of an arc, being the reciprocal of its radius, can be read off immediately by the rule. To meet cases where the curvatures of surfaces are, in opposite directions, the zero, or ∞, is put at the middle of the rule and divided both ways. The chief gain depends on the abolition of cumulative errors due to compass settings, which is effected as follows: The rule is made of a thin slip of transparent celluloid with a small hole at the centre or ∞. A small brass tripod with needle feet is placed so that two feet just penetrate the paper and the third rests on the longitudinal straight line of the strip, which passes through the centre hole, thus forming a temporary but rigid centre about which the rule can rotate. A pen or pencil through the hole at ∞ traces out an arc whose curvature is equal to the reading of the scale where the needle point presses. When the rule crosses the axis of rotation of a generating curve, the numbers representing both curvatures are visible, and the position of the needle-point corresponding to a given total curvature can readily be found. A small arc is then drawn. Holding the strip firmly on the paper, the tripod is moved a little so that the sum of the two readings at the needle point and where the rule crosses the axis has the value corresponding to the position of the tracing point, and another arc drawn. Repeating the process, a very perfect and accurate curve results. Details for drawing nodoids, unduloids, catenoids, and other curves are given in the paper, and many beautiful examples, which had been executed by Miss Stevenson, were exhibited at the meeting. The author also pointed out that the locus of points about which the strip successively turns is the evolute of the curve drawn by the tracing point. Prof. Perry considered the method a new departure of great value. When he (Prof. Perry) drew the capillary surfaces of revolution in 1875, he found that cumulative errors produced considerable discrepancies. Prof. Greenhill said one would now be able to secure better diagrams of transcendental and other curves than heretofore, and he thought Mr. Boys' method would supplant the laborious processes now used to determine the paths of projectiles. Where the resistance varied as the square of the velocity the elevation for maximum range depended on the initial velocity, and for a cube law both elevation and range tend to finite limits as the initial velocity increases. Prof. Minchin inquired whether the catenary could be best drawn by using a scale of equal parts instead of one divided reciprocally. The President greatly appreciated the saving of labour effected by Mr. Boys' method, and thought the apparatus should be shown at the forthcoming exhibition of mathematical instruments in Germany.—Prof. O. J. Lodge, F.R.S., read a paper on the foundation of dynamics, in which he examines the objections raised by Dr. MacGregor (*Phil. Mag.*, Feb. 1893) against the views of Newton's Laws of Motion and the Conservation of Energy, expressed by the author in 1885. The first part of the paper treats of the nature of axioms. An axiom or fundamental law is regarded as a simple statement suggested by familiar or easily ascertained facts, probable in itself, readily grasped, and not disproved or apparently liable to disproof, throughout a long course of experience. On such bases the conservation of energy and of matter rests. Neither can be proved generally, but like other fundamental laws they fit into a coherent and self-consistent scheme, and are therefore worthy of acceptance until they are shown to be wrong. The second part relates to the first and third laws of motion. Dr. MacGregor objects to the first law on the ground that uniform motion is unintelligible unless its direction and velocity are specified with reference to a set of axes, and directly axes are introduced, difficulties occur as to their motion, because there is no satisfactory criterion of rest. Such notions the author deems artificial and unnecessary, except where it is required to define the absolute magnitude and direction of the motion. Reasoning from his own experiments, he believed the ether was at rest, for he had not found it possible to move it by matter. The first law, he said, had been considered unnecessary, as being only a particular case of the second. While admitting the latter fact, he maintained that its separate statement was desirable, on account of its simplicity, and its affording a practical definition of the mode of measuring time. As regards the third law being deducible from the first, he pointed out that if it could be axiomatically asserted that the centre of mass of a rigid system moves uniformly unless an external force acts on the system, then the third law follows. Newton apparently considered it best to state the third law as an axiom, but to many persons it is not obviously axiomatic (some engineers do not accept it), hence its deduction from the other two laws is useful. Part III. of the paper deals with the deduction of the law of conservation of energy from Newton's third law, and universal contact-action. Dr. MacGregor objects to the author's definition of energy as the name given to "work done," and contends that this definition assumes conservation. On this point Dr. Lodge invited criticism, meanwhile pointing out that his definition was analogous to the customary definition of the potential function, and a name for the line integral of a force considered as a quantity that can be stored. On the basis taken, two bodies can only act on one another whilst in contact, hence, if they move, they must move over equal distances; but their action consists of a pair of equal and opposite forces, therefore their activities are equal, and whatever energy one loses the other gains, *i.e.*, energy is transferred from one body to another without change in quantity. In Part IV. the dissipation of energy, the nature of potential energy, and the second law of thermodynamics, are considered. In discussing transference and transformation, "potential energy" is used to indicate the energy of a body under stress, and "kinetic energy," that due to sustained motion. Each corresponds to one of the factors of the product Fv, "activity." So long as one factor is absent no activity can manifest itself, but directly the missing factor is supplied, transference and transformation begin. This was shown to hold in an example of an air-gun with its muzzle plugged, chosen by Prof. MacGregor as an instance of transference of potential energy without transformation. The law of dissipation of energy is stated thus:—"If a body has any portion of energy in such a condition that it is able automatically to leave the body, that portion usually does so sooner or later." Instead of the ordinary form of the second law of thermodynamics the following statement is proposed:—"The portion of energy which a body can automatically part with is alone available for doing work." In discussing this subject the author points out that the common notion that heat engines are much less efficient than water or electric engines is a mistake, arising from the fact that in the one case the efficiency is calculated on the total energy, whilst in the latter cases only the available energy is considered. Two appendices accompany the paper, one the objectivity of energy and the question of gravitation, and the other on more detailed discussion of the transmission of energy in difficult cases.

Chemical Society, May 4.—Dr. Armstrong, President, in the chair.—The following papers were read:—The hydrates of sodium, potassium and lithium hydroxides, by S. U. Pickering. By cooling solutions of sodium hydroxide, the author has succeeded in isolating a number of crystalline hydrates; their formulæ and freezing-points are given in the following table:—

$NaOH, H_2O$	freezes at	64·3°
$NaOH, 2H_2O$	,, ,,	12·5
$NaOH, 3·11H_2O$	,, ,,	2·73
$NaOH, 3·5H_2O$	,, ,,	15·55
$\alpha NaOH, 4H_2O$	,, ,,	7·57
$\beta NaOH, 4H_2O$	,, ,,	− 1·70
$NaOH, 5H_2O$	,, ,,	−12·22
$NaOH, 7H_2O$	,, ,,	−23·51

The hydrate containing 3½ molecules of water is the only one of the eight which has been previously described. In the case of potassium hydroxide two new hydrates have been isolated; these have the formulæ KOH,H_2O and $KOH,4H_2O$, and freeze at 143° and −32·7° respectively. The previously known dihydrate freezes at 35·5°. Lithium hydroxide monohydrate, which was already known, was the only hydrate of this hydroxide isolated.—Detection of arsenic in alkaline solution, by J. Clark. Arsenic acid is not reduced to hydrogen arsenide by zinc dust and caustic potash, or even by sodium amalgam in alkaline solution. No trace of arsenic volatilises on heating sodium arsenate with a large excess of aluminium and caustic soda. The statement of H. Fresenius, that Gatehouse's modification of Fleitmann's test indicates arsenic acid, is hence erroneous; Fresenius's results are probably due to the use of impure aluminium or of arsenic acid containing arsenious acid. The author concludes that none of the methods hitherto proposed for the generation of hydrogen arsenide from alkaline solutions, are available for the detection of arsenic acid.—Improvements in Reinsch's process, by J. Clark. Although Reinsch's process is sensitive to minute quantities of arsenic, and removes all traces of that element from organic mixtures, there are two objections to its use in medico-legal cases. With small quantities of arsenic, the stain obtained is sometimes not easily identified, as the coated copper when heated is apt to give a sublimate of cupric chloride and organic matter instead of arsenious oxide; the method is also not suitable for quantitative estimations, as the whole of the arsenic cannot be volatilised from the copper by means of heat. The author's improvement on Reinsch's process consists in digesting the coated copper with cold caustic potash and hydrogen peroxide, and distilling with ferrous chloride and hydrochloric acid. The arsenic is precipitated in the distillate and weighed as sulphide, whilst any antimony present may be detected in the residual liquor.—The action of light in preventing putrefactive decomposition and in inducing the formation of hydrogen peroxide in organic liquids, by A. Richardson. Several observers have noted that the development of putrefactive organisms is checked by the combined action of sunlight and oxygen; this sterilising influence of light in presence of oxygen has apparently always been regarded as the outcome of an action exerted by the organism. The author has made a number of experiments with urine, in order to ascertain whether, when sterilisation has been effected by light, any oxidising agent, such as hydrogen peroxide, is formed, and whether such substance may not be the sterilising agent. No hydrogen peroxide is produced by the action of oxygen on sterilised urine in the dark, but an appreciable amount of the peroxide is formed on exposing such urine to light; the production of the peroxide is hence independent of the presence of organisms. Substances, such as manganese dioxide, which destroy hydrogen peroxide, greatly facilitate organic growth; the addition of hydrogen peroxide to fresh urine renders the liquid much less liable to change under the influence of organisms, whilst if added to urine in which fermentation has already set in, the peroxide is rapidly decomposed.—The supposed saponification of linseed oil by Dutch white lead, by J. B. Hannay and A. E. Leighton. The author shows that the statement made by several technical writers to the effect that white lead acts on the oil with which it is ground, is erroneous.—Notes on capillary separation of substances in solution, by L. Reed. The author has made experiments on the separation of salts in solution by selective absorption in bibulous paper, using a method differing somewhat from those employed by previous workers. If a drop of a fairly dilute aqueous salt solution is allowed to spread on bibulous paper, a pure water margin is obtained surrounding a sharply defined interior space containing stronger salt solution. The width of the exterior zone is apparently dependent on the nature and concentration of the solution employed; some solutions, such as those of chrome and ammonia alums, give no pure water zone.—Note on a meta-azo-compound, by R. Meldola and F. B. Burls. A comparison of meta-azo-compounds of the formula



where X is an *unsubstituted* hydrocarbon radicle, with the corresponding ortho- and para- series, would be of interest as throwing light on the question of the constitution of organic colouring matters, the "quinonoid" bonds not being present in the meta-compounds according to the present method of formulation. The authors have hence prepared metaphenolazo-α-naphthylamine with the intention of converting it into naphthaleneazo-metaphenol; they have not yet isolated the latter substance and are therefore extending the investigation to other compounds of the same series.—The influence of moisture in promoting chemical action. Preliminary note, by H. B. Baker. The author has continued his investigations on the influence of moisture on chemical action. Ammonia was dried as completely as possible by freshly ignited lime; on then subjecting it to the action of phosphoric anhydride very little of the gas was absorbed. Hydrogen chloride was dried first by sulphuric acid and finally by a week's contact with phosphoric anhydride. On mixing ammonia and hydrogen chloride, dried in this way, *no ammonium chloride fumes were produced* and no contraction was indicated by the mercury gauge attached to the apparatus: it may therefore be concluded that ammonia and hydrogen chloride do not combine when dry. Union at once occurs, however, on introducing a small quantity of moist air. In like manner sulphur trioxide was found not to unite either with lime, barium monoxide, or copper oxide. Furthermore, no brown fumes were produced on mixing dry nitric oxide with dry oxygen.—The genesis of new derivatives of camphor containing halogens by the action of heat on sulphonic chlorides, by F. S. Kipping and W. J. Pope. When the sulphonic chlorides derived from camphor recently described by the authors, are heated at temperatures not very far above their melting points, decomposition occurs and sulphur dioxide is evolved whilst haloid derivatives of camphor remain. In the case of camphorsulphonic chloride, a chlorocamphor melting at 137–138°, is thus obtained. From chlorocamphorsulphonic chloride, a well-crystalline dichlorocamphor melting at 118–119° is formed, whilst bromocamphorsulphonic chloride yields a compound which crystallises in long prisms and melts at 142–143°. These three derivatives of camphor appear to be different from any known compounds and their further study will, it is hoped, throw light on the complex question of isomerism in the camphor series.

May 5, Extra Meeting.—Dr. Armstrong, President, in the chair.—This being the anniversary of the death of Prof. A. W. von Hofmann, the President, after opening the proceedings with a short speech, called upon Lord Playfair, Sir F. Abel and Dr. Perkin to deliver addresses commemorative of Hofmann and his work.

Anthropological Institute, May 9.—Prof. A. Macalister, President, in the chair.—Mr. C. Dudley Cooper exhibited and described the skull of an aboriginal Australian.—A paper by Mr. Charles Hose on Borneo was read. The Baram District, with which the author was most intimately acquainted, is situated in the Northern portion of Sarawak, and the races inhabiting it may divided into four sections:—(1) The low country people and the inhabitants of the coast; (2) the Kayans and Kenniahs, inhabiting the head waters of the Baram River and its tributaries; (3) the Kalabits, living inland; and (4) the Punans, no nomadic tribes, found at the head waters of all the great rivers in Central Borneo. Each of these four divisions comprises a number of sub-divisions speaking different dialects, which can, however, be traced to the same origin. All the various races, except the Punans, employ dogs in hunting. The houses usually stand about twenty feet above the ground supported by huge posts of hard wood; they are some four hundred yards in length, and often hold more than a hundred families. In times gone by the first post put into the ground was passed through the living body of a slave—usually a young girl—but wild animals are now used instead of human beings for this purpose. Mr. Hose exhibited and described a large collection of native implements, weapons, and other objects, and the paper was further illustrated by a number of photographic views shown by the limelight.—Prof. Macalister exhibited a skull from North Borneo.—Mr. F. W. Rudler exhibited a wooden fire syringe from the Malay Peninsula, with a bean tinder box.—Mr. R. G. Leefe contributed a paper on the nivates of Tonga.

Geological Society, May 10.—W. H. Hudleston, F.R.S., President, in the chair.—The following communications were read:—The felsites and conglomerates between Bethesda and Llanllyfni, N. Wales, by Prof. J. F. Blake. The author brought forward fresh evidence in support of the views he had previously expressed as to the Cambrian age of these felsites, and as to the unconformity of the conglomerates on the purple slates. A new tunnel-section at Penrhyn Quarry was described, in which felsite was followed by St. Ann's Grit with a conglomerate-band, and there lying in the midst of the Cambrian series. After a word or two on the conglomerate on Moel Rhiw-wen, the sections on either side of Llyn Padarn were discussed in detail, and it was shown that the distribution of the rocks on the surface of the country could only be explained by the unconformable position of the conglomerates and grits, which, moreover, lie nearly horizontal. After a discussion of the conglomerates of Bettws-Garmon, a detailed section of the adit at Moel Tryfaen was given, in which it was shown that there was only a 3 ft. 6 in. band of conglomerate next the purple slates, followed by 1350 feet of banded slates and laminated grits with four distinct intercalated bands of felsite; and it was argued that the conglomerate on the summit, 55 yards across, could scarcely be represented by this thin band. Finally, the distribution of rocks on Mynydd-y-Celgwyn was shown to be satisfactorily explained by unconformity. Incidentally it was mentioned that a band of rock in the felsite at Llyn Padarn, which had been considered to be a deposited slate, was in reality an intrusive igneous rock. The conglomerates described were considered to be an overlap of the Bronllwyd Grit. The reading of this paper was followed by a discussion, in which the President, Prof. Hughes, Mr. Rutley, Mr. Marr, and the author took part.—The Llandovery and associated rocks of the neighbourhood of Corwen, by Philip Lake and Theo. T. Groom. The area described forms a part of the northern slope of the Berwyn Hills, and stretches along the southern bank of the Dee from Corwen to Pen-y-glog. The beds of the Berwyns are here thrown into a series of folds which run nearly E.-W.; and the northerly limbs of these folds are long and low, while the southerly limbs are short and steep. The folds are cut through by a number of faults which run nearly E.-W., generally along the crests of the anticlinals, and these invariably throw down towards the north. The southern bank of the Dee Valley is here formed by these faults. A second series of faults running about 20° W. of N. to 20° E. of S. is of later date. One of these, near Corwen, presents some peculiar features, since its downthrow in some places is on the east and in others on the west. The lowest beds present are bluish slates, with numerous Bala fossils. These are succeeded immediately by the Corwen Grit of Prof. Hughes. No fossils have been found in this at Corwen; but in a grit occupying a similar position at Glyn Ceiriog numerous fossils have been discovered. The Corwen Grit is succeeded by grey slates with grit-bands; and in Nant Cawrddu, near Corwen, and Nant Llechog, near Pen-y-glog, these slates are followed by banded black shales containing numerous graptolites of the *Monograptus gregarius*-zone. Above these are pale bluish slates; and nothing further is exposed till we reach the Tarannons. The Corwen Grit clearly forms the base of the Llandovery in this area, as suggested by Prof. Hughes. Some remarks were made on this paper by the President, Prof. Hughes, Mr. Groom, and Prof. Lapworth. Mr. Lake briefly replied.

Zoological Society, May 16.—Osbert Salvin, F.R.S., Vice-President, in the Chair.—Extracts were read from a letter addressed to Prof. Newton, F.R.S., by Prof. E. C. Stirling, of Adelaide, respecting the recent discovery of a large series of remains of *Diprotodon*, *Phascolomys*, and other Mammals at Lake Mulligan, in South Australia, about 600 miles north of Adelaide. It was anticipated that when these remains were received and examined very important additions to our knowledge of the extinct Mammal-fauna of Australia would follow.—Mr. Beddard, F.R.S., read a paper upon the structures termed "atrium" and "prostate" in the Oligochætous worms, in which reasons were given for believing that all these structures were reducible to one common plan.—Mr. G. B. Sowerby read the descriptions of fifteen new species of shells of the family Pleurotomidæ from different localites.—A communication was read from Mr. A. H. Everett, containing a revised list of the Mammals inhabiting the Bornean group of Islands, that is, Borneo, and Palawan, which, as Mr. Everett had shown in a previous paper, belongs zoologically to Borneo.—Mr. O. Thomas read a paper containing an account of a second collection of Mammals sent by Mr. H. H. Johnston, from Nyasaland. The present series (collected, like the former, by Mr. Alexander Whyte), consisted of about 75 specimens, referable to 30 species, of which a large proportion were additional to the fauna of Nyasaland.—Dr. P. Sonsino, of Pisa, read some notes on specimens of parasitic worms of the genus *Distomum*, of which he had lately examined specimens.

Royal Meteorological Society, May 17.—Dr. C. Theodore Williams, President, in the chair.—The following papers were read:—Mean daily maximum and minimum temperature at the Royal Observatory, Greenwich, on the average of the fifty years from 1841 to 1890, by Mr. W. Ellis. The author gives tables of the mean maximum and mean mimimum temperature of the air on each day of the year, and also tables showing the daily range of temperature and the mean of the daily maximum and minimum values.—Suggestions, from a practical point of view, for a new classification of cloud forms, by Mr. F. Gaster. The forms assumed by clouds at different levels and under various conditions have recently received considerable attention from meteorologists. The author, however, does not approve of the nomenclatures and classifications which have been proposed, as, in his opinion, they appear to be little, if any, better than the older ones they were intended to replace. He now proposes a somewhat different classification, arranging the clouds according to altitude under the following headings:—(1) Surface clouds, or those which appear commonly between the earth's surface and a level of about 2000 feet; (2) Lower medium clouds, including all varieties which usually float at an elevation ranging from 2000 to about 10,000 feet; (3) Higher medium clouds, or those commonly found at altitudes varying from 10,000 to about 22,000 feet; (4) Highest (or cirriform) level clouds, or those at elevations exceeding 22,000 feet. The author gives the names of each variety of cloud included in the classification, together with an account of the principal characteristics of each as far as appearance goes.—Notes on winter, by Mr. A. B. MacDowall. In this paper the author discusses the question of periodicity in winter at Greenwich and Paris, and the relation of summers to winters.

PARIS.

Academy of Sciences, May 23.—M. Lœwy in the chair.—The Permanent Secretary announced the death, at Berlin, of Herr Kummer, Foreign Associate, and M. Hermite gave a review of the work of the celebrated geometrician. Herr G. Wiedemann was elected correspondent for the section of physics, in the place of Herr W. Weber, deceased.—On the kinetic theory of gases, by M. H. Poincaré. A correction of Maxwell's proof of the law of adiabatic expansion.—Note by M. Berthelot, accompanying the presentation of his work, "On the Chemistry of the Middle Ages."—On some rare or new natural phosphates; brushite, minervite, by M. Armand Gautier. A new lime and alumina phosphate was found among the concretionary phosphates of the *Grotte de Minerve*. Microcrystalline like most of these substances, soluble in dilute mineral acids, in weak potash lie, and in alkaline ammonium citrate, except a slight clayey residue, it has a different composition from the other natural aluminium phosphates, and has been called Minervite to recall its place of discovery.—Determination of the water contained in soil carrying various crops after a period of great drought, by M. Reiset.—Observation of the total solar eclipse of April 16, 1893, made at Joal (Senegal), at the observatory of the expedition of the Bureau des Longitudes, by M. G. Bigourdan.—On the investigation of the solar corona apart from total eclipses, by M. H. Deslandres.—On a highly sensitive manometric apparatus, by M. Villard.—The heat spectrum of fluorspar, by M. E. Carvallo.—Dynamical phenomena due to the residual electrification of dielectrics, by M. Charles Borel.—On chloroborate of iron and on a method of preparing chloroborates isomorphous with boracites, by MM. G. Rousseau and H. Allaire. The method consists in letting a volatilised metallic chloride act at a red heat upon natural calcium borate or upon borosodiocalcite. In the case of iron, the product obtained corresponds sensibly to that of a boracite in which the magnesium has been replaced by iron, according to the formula $6FeO.8B_2O_3.FeCl_2$. The chloroborate of iron crystallises in transparent cubes of a greyish colour, which act upon polarised light. This optical property shows that these crystals, like those of natural boracite, present a pseudo-cubic symmetry. They dissolve slowly in nitric acid and are rapidly disintegrated by fused alkaline carbonates.—On the heat developed in the combination of bromine with some unsaturated substances of the fatty series, by MM. W. Louguinine and Irv. Kablukov. Calorimetric determinations carried out in the cases of trimethylethylene, hexylene, diallyl, allyl alcohol, and allyl bromide led to the following conclusions: The heat developed by their combination with bromine increases as one proceeds upwards in the homologous series. The presence of an atom of Br replacing H in the unsaturated hydrocarbons mentioned, considerably reduces the rapidity of the addition reaction of the bromine. In presence of the OH group the addition reaction ceases to be sharply defined and is accompanied by a substitution reaction.—On licarhodol derived from licareol, by M. Ch. Barbier.—Action of sodium sulphite upon the amidophenol salts; new method of obtaining amidophenols from their salts, by MM. Aug. Lumière and A. Seyewetz.—Ptomaïn extracted from urines in eczema, by M. A. B. Griffiths.—On δ-achroglobine, a respiratory globuline contained in the blood of certain Mollusca, by M. A. B. Griffiths. In addition to the α-achroglobine extracted from the blood of Patella, the β variety from the Chitons, and the γ variety from the Tunicata, a fourth variety, δ-achroglobine, has been discovered in the blood of certain species of Doris. 100 grammes of this substance absorb 125 cc. of oxygen at 0° and 760 mm. Its empirical formula is $C_{659}H_{792}N_{165}SO_{153}$.—On the Plankton of the northern lagoon of Jan Mayen, by M. G. Pouchet. The island of Jan Mayen possesses two lagoons formed by fresh water due to the melting of the glaciers, and separated from the sea by narrow dykes of sand and shingle. The southern lagoon is of recent date. At the time of discovery it was an open bay. The northern lagoon was explored by the steamer *La Manche* in July 1892. By means of a fine net the central portion was tested for any surface life (Plankton) that might have escaped the Austrian expedition, which had failed to discover any. As the result of prolonged work a few species were found, including a Conferva, Infusoria allied to Paramecium and Actinophrys, a Tardigrade, a Copepod, and numerous Rotifers.—Dimorphism in the development of hemosporidia, by M. Alphonse Labbé.—On the scented mists observed on the coasts of the Channel, by M. S. Jourdain. These mists occur in spring under a northeast wind, and usually in the morning. The appearance is that of a bluish-grey vapour, and the smell that of lime-kilns. The air is very dry while they last. The author thinks that they are cosmic, not local phenomena.

BERLIN.

Physiological Society, May 5.—Prof. du Bois Reymond, President, in the chair.—Dr. Schmidt spoke on the colour-reactions of the excreta, whereby the mucin exhibits certain very characteristic and distinctive differences, as compared with proteids.—Prof. Fritsch exhibited a number of lantern-slides of the electric organs of Torpedo, Malapterurus, and Gymnotus, by which he had determined the structure of the giant ganglia, the axis cylinders which arise from these and are distributed to the electric organ and the protoplasmic prolongations, which either form a means of connection between neighbouring ganglia, or else resolve themselves into an anastomosing network.—Dr. Benda also exhibited projections of micro-photographs, in linear magnification of 2000 to 3000 diameters, of the testis of Salamanders in illustration of the formation and fate of the karyokinetic nuclear rods.

Meteorological Society, May 9.—Dr. Vettin, President, in the chair.—Prof. Hellmann presented the two first numbers of reprints of important papers on meteorology and terrestrial magnetism, which he is publishing with the support of the German Meteorological Society and the branch society in Berlin. No. 1 is a *fac-simile* of the earliest German work on meteorology: Weather-book by Rynmann, dated 1510. No. 2 is also a *fac-simile* of Bl. Pascal's celebrated research by which the existence of atmospheric pressure was first determined.—Prof. Börnstein spoke on the most recent theories as to thunderstorms, of which none supply a definite solution of the problems involved, and explained a simple form of apparatus by Elster and Geitel, in Wolfenbüttel, by means of which anybody can make observations on atmospheric electricity, and invited the co-operation of the members.—Dr. Kremser gave some notes on the dryness of last April. Whereas the average fall in Prussia for April is 30 to 50 mm., the fall for last month was only 10 mm. in the extreme east, falling to 1 mm. in the central region, and to 0 mm. in the west and south-west. In Berlin a measurable amount of rain fell on only one day, the 17th, amounting to 0·5 mm., so that this month was the driest recorded since observations were first made in Berlin. Up to the present time the driest month had been October, 1865, with a fall of 1 mm. The period of drought began as early as March 21 or 22, and in many parts of Prussia had lasted for forty days, being accompanied by absence of clouds and marked temperature amplitudes of 10° to 18°.—Dr. Less gave an account of the barometric conditions over Europe during the drought. They may be divided into three periods. In the first, at the end of March and beginning of April, the highest pressure lay over France and Germany, the lowest over Russia as far as the Ural Mountains. In the second period, the middle of April, the area of high pressure had moved over towards England, while the lowest pressure had extended to the centre of Germany. In the third period a flat area of lowest pressure situated over the Atlantic had driven the area of highest pressure once more towards central Europe.—Prof. Börnstein exhibited samples of the material used in the construction of the recently-destroyed balloon "Humboldt." This balloon had become ignited, accompanied by a violent explosion, while being emptied, without any definitely ascertainable cause. The speaker demonstrated how readily the outer surface of the material could be electrified by friction, and suggested that electricity had thus been generated, and had, as a spark-discharge, ignited the gas as it escaped. This source of danger could probably be removed by placing a few long metallic wires round the valve.

DIARY OF SOCIETIES.

London.

THURSDAY, June 1.

Royal Society, at 4.30.—On the Colour of Sky-light, Sun-light, Cloud-light, and Candle-light: Captain Abney, F.R.S.—Flame Spectra at High Temperatures; Part I., Oxyhydrogen Blowpipe Spectra: Prof Hartley, F.R.S.—Note on the Flow in Electric Circuits of Measurable Inductance and Capacity; and in the Dissipation of Energy in such Circuits: A. W. Porter.—On the Metallurgy of Lead: J. B. Hannay.—On the Motion under Gravity of Fluid Bubbles through Vertical Columns of Liquid of a Different Density: F. T. Trouton.

Linnean Society, at 8.—On Polynesian Plants collected by J. J. Lister: W. B. Hemsley, F.R.S.—On the Anatomy of a New Plant—Melastomaceæ or Gentianaceæ, Genus Novum: Miss A. Lorrain Smith.—Observations on the Temperature of Trees made in Boulder, Colorado: Dr. Baur

Chemical Society, at 8.—Azo-Compounds of the Ortho Series: Prof Meldola, F.R.S, E. M. Hawkins, and F. B. Burls—The Fluoresceïne of Camphoric Anhydride: Dr. Collie.—The Action of Phosphoric Chloride on Camphene: J. E. Marsh and J. A Gardner.—The Composition of Jute produced in England: A. Pears, jun.

Royal Institution, at 3.—The Geographical Distribution of Birds: Dr. R. Bowdler Sharpe.

FRIDAY, June 2.

Geologists' Association, at 8.—Consideration of the Principal Phenomena connected with Volcanoes: Dr J. W. L. Thudichum.

Royal Institution, at 9 Study of Fluid Motion by Means of Coloured Bands: Prof. Osborne Reynolds, F.R.S.

SATURDAY, June 3.

Royal Institution, at 3.—Falstaff—a Lyric Comedy by Boito and Verdi (with Musical Illustrations): Dr. A. C. Mackenzie.

Institute of Actuaries, at 3.—Annual Meeting. - Report of the Council for the Past Year and Election of Officers and Members of Council.

MONDAY, June 5

Society of Chemical Industry, at 8.—The Movement of Air as applied to Chemical Industries: H. G. Watel.—New Cellulose Derivatives and their Industrial Applications: C. F. Cross and E. J. Bevan.

Royal Institution, at 5.—General Monthly Meeting.

TUESDAY, June 6.

Zoological Society, at 8.30.—Notes on the Anatomy and Classification of the Parrots: F. E. Beddard, and F. G. Parsons.—On Two Horns of an African Rhinoceros: Mr. Sclater.—On some Bird-Bones from Miocene Deposits in the Department of Isère, France: R. Lydekker.—On the Osteology of the Mesozoic Ganoid Fish, Lepidotus: A. Smith Woodward.

Royal Institution, at 3.—The Waterloo Campaign: E. L. S. Horsburgh.

WEDNESDAY, June 7.

Geological Society, at 8.—The Bajocian of the Sherborne District; its Relations to Subjacent and Superjacent Strata: S. S. Buckman.—On Raised Beaches and Rolled Stones at High Levels in Jersey: Dr. Andrew Dunlop.

THURSDAY, June 8.

Royal Society, at 4.30.

Mathematical Society, at 8.—Complex Integers derived from $\theta^3-2=0$: Prof. G. B. Mathews.—Pseudo-Elliptic Integrals: Prof. Greenhill, F.R.S.

Royal Institution, at 3.—The Geographical Distribution of Birds: Dr. R. Bowdler Sharpe.

FRIDAY, June 9.

Physical Society, at 5.—A New Photometer: A. P. Trotter.—Notes on Photometry: Prof. S. P. Thompson, F.R.S.—The Magnetic Field near a Wire: Prof. G. M. Minchin.

Royal Astronomical Society, at 8.

Royal Institution, at 9.—The Recent Solar Eclipse: Prof. T. E. Thorpe, F.R.S.

SATURDAY, June 10.

Royal Botanic Society, at 3.45.

Royal Institution, at 3.—Falstaff, a Lyric Comedy by Boito and Verdi (with Musical Illustrations): Dr. A. C. Mackenzie.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—Year-Book of the Scientific and Learned Societies of Great Britain and Ireland (Griffin).—Graphic Arithmetic and Statics: J. J. Prince (Murby).—Erdbebenkunde: Dr. P. Hoernes (Leipzig, Veit).—Introduction a L'Electricité Industrielle—Potential, Flux de Force Grandeurs Electriques; Ditto, Circuit Magnétique;—Induction Machines: P. Minel (Paris, Gauthier-Villars).—The Theory of Telescopic Vision: E. M. Nelson (Dulau).

Pamphlets.—Wetterbüchlein von Wahrer Erkenntniss des Wetters: L. Reynman (Berlin, Asher).—Récit de la Grande Expérience de l'Equilibre des Liqueurs: B. Pascal (Berlin, Asher).—The New Priesthood: Ouida (E. W. Allen).

Serials.—Bulletin of the New York Mathematical Society, vol. 2, No. 8 (New York, Macmillan).—Internationales Archiv für Ethnographie, Band 6, Heft 2 (K. Paul).—Bulletins de la Société d'Anthropologie de Paris, tome troisième, iv. série, 4e Fasc.; Ditto, Nos. 2,3, 4 (Paris, Masson).

CONTENTS.

THURSDAY, JUNE 8, 1893.

THE ROYAL SOCIETY ELECTION.

HAD it not been for the unnecessary and indiscreet communication to the newspapers of a letter not intended for the public eye, the difference of opinion which made itself manifest at Burlington House last Thursday might have been settled in a purely domestic manner. As it was, it gave rise to comments which, in most cases, were as absurd as they were painful to the persons concerned. But the mischief is done and it would be affectation to deny that a question of considerable moment has been raised and one which will very probably provoke in the future a good deal of discussion and consideration. Clearly, therefore, it has to be faced, and I willingly accede to the wish of the Editor of NATURE to state why I think the policy of the dissentients should not be accepted by the general body of the Fellows of the Royal Society.

I say policy, because I think it must be obvious to every one that the matters involved go a good deal deeper than the personal interests which were at stake. And here I would say at once that looking at the names of the dissentients, it is impossible to suppose that those who proposed to reject the recommendations of the Council were animated by anything but perfect good faith, and a real desire to act in the best interests of the Royal Society. Though I entirely disagree with them, I say this with the more conviction as they were nearly all my own personal friends. The harshest thing I should be disposed to say of their action is that while it had the uncompromising honesty, it also had the unreasonable narrowness of a somewhat provincial point of view.

Every one will I suppose admit that in most administrative matters the English people are above all things practical and are little influenced by considerations of either logical order or of mere symmetry. The Royal Society appears to be a notable case in point. It is unlike any analogous institution, as far as I know, in the world. It is by no means a mere Academy of Science. Looked at historically and from the point of view of actual facts, it is seen to be an association of persons of "light and leading" who wish to promote the interests of science especially in so far as they are a matter of national concern. I use deliberately the rather hackneyed words "light and leading" as descriptive of the qualifications of its members. They fall in fact into the two categories; on the one hand they consist of the most competent experts in different branches of science and on the other of prominent men in the political and social world who are sympathetic to science and desirous of promoting its progress as an indispensable phase of our life and intellectual development as a nation.

Now it seems to me that the real importance of the proceedings of last Thursday was the attack which was virtually made and with some vigour on this position. The dissentients in their printed statement completely ignored its existence. I can only make the excuse for them which Dr. Johnson made when a lady asked him to account for a very palpable blunder in his dictionary. "Ignorance, ma'am, sheer ignorance." It seems therefore worth while to show that in including in the fifteen selected candidates a man of public distinction who was not a professional man of science the Council acted in accordance with well-established tradition and precedent which has not hitherto been seriously challenged.

In other countries where Government is constituted on more bureaucratic lines than it is in this, men of science associate themselves in bodies to which non-scientific members of the community have no access. Such bodies can address the state, and are doubtless listened to with the respect due to expert authority. But the reason is mainly because science under such conditions falls into line with general bureaucratic arrangements. In England the expert as such is more usually listened to with hesitation. It is my belief that if the Royal Society were simply constituted of professional scientific men, its influence in the country would be vastly diminished. Englishmen are distrustful of experts whom they think, and I must admit too often with justice, to be cramped in their general outlook and wanting in knowledge of the world. Furthermore Englishmen are curiously shy of what they don't comprehend. A purely professional Royal Society would be apt to be treated with a kind of ironical respect but otherwise severely left alone as a thing "no fellow can understand."

Now it may be asked reasonably, would this be a desirable state of things? I think it may be shown with little difficulty that in the interests of scientific progress in this country it would not. Consider for a moment the kind of work which the Royal Society does. In the first place, and I suppose the dissentients would say that this is its only proper function, it signalises and marks out those workers in science as to whose integrity and competence it has satisfied itself. But this might be done by a small and exclusive club, and though such a body would be distinguished, it would never enjoy the distinction which attaches to the Royal Society. That distinction rests on the fact that it possesses a quasi-official position in the State. It is therefore on the one hand able to approach the Government of the day with a recognised status and authority to speak; on the other hand it is the supreme scientific tribunal from which the Government can count on obtaining a perfectly impartial judgment on questions of importance to the community. Here it may be replied that a strictly-restricted scientific Academy could equally fulfil those functions. In any other country, I have already admitted that it may be so. But here again national peculiarities must be reckoned with. In this country most important Government business is in all essential features settled in a semi-official way. Preliminary *pour-parlers* ascertain what applications would be acceptable and what will be conceded to them. The official letters which are ultimately exchanged only put on record what has been previously negotiated. It is here that the presence of what I may call a sympathetic lay element in the Society is so invaluable. A statesman or public man by becoming a fellow has solemnly pledged himself to co-operate with his colleagues. A minister therefore who is an F.R.S. cannot refuse, in common courtesy, to lend his ear to representations to which as a politician he might be very willing to be deaf.

No doubt there was a time when this lay element tended to swamp the Society and to destroy its scientific prestige. But the Royal Society is not a thing of yesterday; and accumulated experience has shown the way to the present *modus vivendi* which appears to me to have given the maximum advantage to the scientific world over which the Society presides without the remotest possibility of injurious interference.

It may be well to consider in what this lay element consists. In the first place we have the Sovereign who was the Founder and is always the Patron and may in the future as in the past take an active part in the Society's proceedings. Next there are the Princes of the Blood any one of whom may at any time be summarily proposed for election. The original statutes provided that any one of the rank of Baron or higher should be qualified for election. That privilege was however abolished in the present century, no doubt as opening the door to the lay element too widely. But the privilege was retained for the Privy Council, a body which in its constitution is analogous to the Royal Society inasmuch as access to it can only be obtained outside the Royal Family by conspicuous ability independently of mere rank or birth. And it may be noticed that the analogy is drawn even closer by the recent admission to the Privy Council of a scientific element. Each body has in fact in relation to the State its own field of activity and functions. But they are often not very dissimilar. A committee of the one body may advise the Government on the constitution of a new university; a committee of the other may equally advise it on the methods of obviating explosions in mines. We may have a Privy Councillor discussing at Burlington House Marine Signals or Colour Vision, while a late president of the Society may be occupied at Whitehall in determining whether the Eternity of Future Punishment is a binding article of the English faith.

But besides members of the Privy Council it has been the custom time out of mind to elect into the Society as ordinary fellows men of conspicuous public position and merit, with the proviso, however, that they should in their careers have shown themselves sympathetic to science. Such elections, however, differ *in toto* from the honorary and merely complimentary degrees conferred by the Universities. Such men are brought into the Society, first, in recognition of their services to science, secondly, to confirm them in their interest in it, lastly, that their cooperation may be secured in the performance of the Society's public work. The Society in order to effectively accomplish that for which it exists must be in touch with other fields of national life; it requires and turns to good account its connections with society, with the legislature, with the bench, with Government administration. By including in their number a body of distinguished public men, the Fellows of the Royal Society are able to enormously enlarge their influence and to display themselves as reasonable if hard-headed men of the world, perfectly able to play their part in affairs which concern them on equal terms with those who make the conduct of affairs their only business and by no means as mere recluses in a laboratory. Can any more effective mode be imagined for removing from scientific men that suspicion of impracticable pedantry with which men of science are too often regarded by the uninformed?

In the face of these considerations which I had thought were part of the well-known traditions of the Society I confess that the hubbub of last Thursday somewhat amazed me. It was fought over a man who is preeminently of the kind that the Royal Society has been always willing to coopt. A man of singular modesty but vast learning, a scientific historian with the keenest sympathy for science, a member of the legislature who by his own unaided merit has acquired for himself a conspicuous position amongst the statesmen of the day. If the principle of the admission of laymen is admitted at all, who could be more suitable?

The simple fact is that there was nothing anomalous in the matter. Any one who has taken part in the selection of candidates by the Council will know that there is a regular category for lay candidates presented on their public form. The Council has to make up its list with due regard to the claims of every branch of science. But I think I cannot be far wrong if I assert that in most recent years it has been the practice to select on an average one layman annually. There are at least a dozen in the existing list and the obituary notices abound with them. It is perhaps invidious to mention names but I may single out of those living Sir Henry Barkly, Sir William Jervois, Sir John Kirk, Sir George Nares, Sir Bernard Samuelson, Sir George Verdon, Sir Charles Warren. Any of these men would probably disclaim any pretension to be considered a professional man of science. But each and all of them has rendered great services to it, and the recognition of this by the scientific world is the best way to get other distinguished public men to imitate their example.

If I have discussed the question at some length it is because it seems to me to be one of vital importance to the welfare of the Society. But the dissentients took a further step which if it were to become a precedent would be absolutely disastrous. They not merely proposed that one of the candidates selected by the Council should be rejected but without consulting him proposed that another whom the Council had not recommended should be elected. It is true that in their first circular the dissentients stated that the statutes of the Society left no other course open to them. This however is an entire mistake and I am afraid is rather characteristic of the want of due consideration which characterised the whole proceeding.

It appears to me, putting other considerations aside, unlikely that in so delicate a matter any five fellows can arrive at a sounder conclusion than the twenty-one who form the Council. Any fellow who has been a member of that body must have been struck with the frankness and impartiality with which the merits of the respective candidates are weighed and discussed. And so large a proportion of the Council is changed every year that it would be practically impossible for it ever to come under the control of any one party in the Society, if there be such a thing. It appears to me therefore that all presumption is in favour of the judgment of the Council and I think that experience has shown that in the vast majority of cases it has been exercised wisely.

It will be generally agreed that in no branch of science can those who follow it arrive at a correct estimate of the merits of those who work in other branches without the responsible evidence of men with the necessary technical knowledge. Now this testimony the Council both receives and has the opportunity of carefully sifting. Having arrived at a judgment accordingly, it appears to me that that judgment should not be lightly upset unless in the almost inconceivable case of its being utterly outrageous.

Councils have erred in the past, and I suppose the Council of the Royal Society cannot claim infallibility. It might be necessary therefore for the general body of fellows to correct its action. The election of a fellow is an irretrievable step. To oppose it is a grave but it may be a justifiable procedure. But to over-ride the Council's discretion in not selecting a particular candidate is a much graver one. Non-selection is not an irretrievable injury and if in any one year it may seem to inflict some injustice on a particular candidate its redress when justified by merit is not difficult of attainment on a subsequent occasion. But if a precedent were established for taking the matter out of the hands of the Council, peace and good feeling in the ranks of the Society would soon vanish. In time every election would be the occasion of a conflict and no one who valued his self-respect would care to serve on the Council. Nor is there any reason to think that any substantial gain would accrue. A man may be rushed to the front by a wave of temporary and emotional popularity. Such a man, if the fellows acquired the habit of meddling with the Council's prerogative of selection, might be forced prematurely upon the Society. In the long run it is not improbable that those who resorted to such a practice might live to regret their precipitancy. W. T. THISELTON-DYER.

VERTEBRATES OF ARGYLL AND THE INNER HEBRIDES.

A Vertebrate Fauna of Argyll and the Inner Hebrides. By J. A. Harvie-Brown and T. E. Buckley. (Edinburgh: David Douglas, 1892.)

PERTINACITY in an endeavour to carry out the results of a fixed idea has almost always been regarded as a virtue, even when the principle involved has seemed to be hopelessly mistaken, and thus the adherents of the Stuart and other lost causes still find sympathisers at the present day; but when none can doubt the value of the idea, the pertinacity with which it is supported, provided that obstinacy is left out, becomes a virtue that in these practical days is not easily exaggerated. Such pertinacity is conspicuously exhibited by the authors of the book before us, Mr. Harvie-Brown and his worthy coadjutor, Mr. Buckley. This "Vertebrate Fauna of Argyll and the Inner Hebrides" is the *fifth* of a series of volumes, the inception of which is vastly creditable to its founder, the gentleman first named, and to all concerned in its production—even to the printer's devil and the binder's apprentice. Some of its predecessors have before received notice in these columns;[1] but it has perhaps never been made clear to the readers of NATURE that this series of books is placing the zoology of the northern Kingdom on a footing which has not been attained, nor is likely to be attained in the southern part of the island, even though there exist particular English works—but this solely so far as ornithology is concerned—of merit superior to any one of the Scottish productions, the volume on Orkney, which is of remarkable excellence, being perhaps an exception. It is not difficult, however, to account to a considerable extent for this superiority: the proportion of persons with a taste for natural history to the general population being presumably the same in both parts of Great Britain, the enormously greater population of England would naturally furnish a larger number than Scotland is able to show. This is not said in derogation of the northern kingdom. It has always been rich in botanists; and, among zoologists, the single name of William Macgillivray is enough to cover it with renown. However much his merits, and especially his originality, may have been obscured or underrated in his life-time, he has already been recognised by those who have taken the trouble to inform themselves, and especially by American writers, as the most original British worker in regard to the vertebrate division of animals, since the incomparable pair—Willughby and Ray. But of Macgillivray this is not the place to speak particularly. On some other occasion we hope we may say more of him, a man whose work by some unhappy fate failed to impress his contemporaries, and whose posthumous volume was oppressed by princely patronage—well-meant but ill-advised. He had little or no experience of "Argyll and the Inner Hebrides," and really does not now come into our story.[1]

As a matter of fact it is hard to say who among old naturalists does deserve especial mention in connexion with the Faunal District of which this volume treats. Mr. Harvie-Brown, with the caution characteristic of his nationality, abstains from putting forth the claim of any predecessor; though, as brave men lived before Agamemnon, this district may have had a zoological historian before the laird of Dunipace and Quarter. The late Mr. Henry Davenport Graham—an honest observer if there ever was one—whose pleasant contributions to the ornithology of Iona and Mull, illustrated by some of his humorous and very clever sketches, were published in 1890 as a "relief volume" of the present series, belongs of course to the existing epoch, for he died in 1872; and moreover his observations were confined to but a small portion—the islands just named—of the district. Thus as regards its ancient history from the zoological point of view, we have an absolute void, since the Statistical Accounts (both Old and New) of the county of Argyll and the Isles give as little information to the purpose as does the often-quoted but seldom-read description of Dean Monro, which was only published in 1774, 225 years after it was written.[2]

To come to closer quarters, we are inclined, though we must say so with diffidence, to question Mr. Harvie-Brown's delimitation of his "Faunal District." In principle he is undoubtedly right, though somehow or other the result does not seem to work out well. His principle was laid down in the first volume of the series—that on Sutherland, Caithness, and Western Cromarty—and is the marking out of a district by physical features rather than by political boundaries. No naturalist ought

[1] "A Vertebrate Fauna of Sutherland, Caithness, and West Cromarty," NATURE, xxxi. p. 292; "A Vertebrate Fauna of the Outer Hebrides," NATURE, xl. p. 101.

[1] His portrait is given by our authors in their volume on "The Outer Hebrides."

[2] A reprint of this very rare work was published at Glasgow in 1884 (by Thomas D. Morrison).

to hesitate for a moment in preferring a watershed to a wapentake, since the former has natural limits, while those of the latter may be the consequence of a chapter of accidents. Moreover watersheds, though sometimes difficult to trace and lay down on a map, are as a whole much more to be trusted than some other kinds of boundaries, notably more so for instance than rivers, which in biology, with very rare exceptions, do not furnish a scientific frontier; but some wise man of old has remarked that there is reason in the roasting of eggs, and the faunist certainly ought to exercise some discretion in choosing his watersheds. What difference there may be in the land-fauna of the two sides of the peninsula of Cantire, for instance, we are at a loss to conceive, and yet we have our author's line of demarcation driven remorselessly along its summit ridge from its Mull to West Tarbert, and thence northward, splitting Knapdale in like manner, and shutting out from Argyll the home of Maccallum More—Inveraray itself! If the eastern half of Cantire, with Arran, Bute, Cowall, and goodness knows what beside, are to form another separate district, something may be urged for this view, but if they are to be annexed to Carrick, Kyle and Cunningham—in a word to Ayrshire and the South-West of Scotland, we feel bound to protest against the proceeding as an unnatural union. Arran undoubtedly agrees far more in every essential faunal character with Ardnamurchan than with Ayrshire—that much we venture to affirm, even if we should be sorry to attempt a delimitation between the districts of "Argyll" and "Clyde" further to the northward, or between "Argyll" and "Forth"; but though, as we have said above, we attach great importance in many cases to watersheds, we are inclined to hold ourselves entitled to cut *across* valleys on occasion, and because Loch Lomond drains to the "Clyde" and Loch Katrine to the "Forth," it does not at all follow as a rule, that their upper levels belong to the districts which contain their "carses." In other words the basin plan of dividing a country may be overstrained. Still we gladly admit that the fault is on the right side, and considering the extraordinary way in which so many of its counties interlock, it would be manifestly misleading to attempt to treat Scotland according to the method which is on the whole suitable enough for England, where the counties are much more continent. There is the old story of the man, possibly, it is true, an ignorant southron, who wished to explore Cromartyshire, but never succeeded in finding more than bits of it!

To the naturalist islands have a peculiar fascination of their own, and it is quite pardonable therefore in our authors that, in the introductory portion of their volume, they should devote more space to the description of the Inner Hebrides than to Argyll, properly so called, especially when, as we have already stated, the delimitation of their district cuts off so much of what most people would include therein. Yet thereby they recall the celebrated story told by Sir Walter Scott of the Minister of Cumbrae, which we forbear from repeating; and we must say that in their infinite mercy they might not have so wholly overlooked the interest that appertains to the adjacent mainland. Ardnamurchan, before mentioned, receives its due, but Moidart and Morven, Ardgour and Lochaber, Ben Nevis, the loftiest peak in Great Britain, and the historic Glencoe, the gloriou Loch Etive and the beautiful Loch Awe, receive but scan attention. However our authors have given us, and we are thankful for it, the portrait of two inhabitants of the mainland—the late Peter Robertson and his pony—though, not a word being vouchsafed to show why they are thus honoured, many who take up the volume may wonder at the preference shown to them. The present writer cannot trust his recollection for equine likenesses, but if the beast figured (at p. xii. of the "Preface") was that which bore him on a never-to-be-forgotten day, more than thirty years ago, he has no objection to urge; and undoubtedly the man was worthy of being thus commemorated since, throughout Scotland, no one was more famous for his knowledge of Red Deer than the head-forester of Mona Dhu—the "Black Mount"—while his intimate acquaintance with the animal life of a characteristic Highland district was no less good, and one could not be in his company for half an hour without recognising in him the true naturalist. He was wholly different from the much-writing and much-bewritten "Field Naturalist" of the type with which we have lately become painfully familiar, the man who is all eyes and tongue but has no brains, thinking everything he sees is seen for the first time, and is worth publishing abroad because he has seen it. From one point of view this man is not wrong, since it pays well to contribute a sensational article so based to a nonscientific magazine, while he can do this in safety, for no naturalist will be at the trouble to hurt his feelings by pointing out that what he writes contains nothing more than was known before, and that his specious verbiage alone is new. "Mr. Robertson"—to speak of him as he was spoken of by those who for many years lived under his mildly despotic rule—was a man of retiring character and plain speech, possessed of that admirable manner which, if not inborn, comes only from mixing with all classes of society. He would address a prince of blood royal without a trace of servility, or a cockney sportsman without exciting suspicion of contempt. The *mens sibi conscia recti* kept him from either failing. To no smattering of science did he make pretence, and it was with wonder that he received the application to communicate the results of his experience as to Red Deer to the editor of Macgillivray's unhappy posthumous work already mentioned. Would that the whole of it had been published there! No one could listen to his conversation without perceiving that as an observer of nature he had not wasted his life, and that he had thought over, if not thought out, problems that have puzzled and still may puzzle the best informed of naturalists. But this is enough of him, and we have only said it because our authors have said nothing. We must return to what they tell us.

It is hardly to be doubted that to the naturalist the most interesting of Scottish mammals are the *Phocidæ*—the Seals, and it is curious to look back upon the obscurity in which they were involved until comparatively few years ago—not that we would have any one to suppose for a moment that there is not plenty more to be learnt about them. It is probably not yet known to the majority of British zoologists that, apart from all possible or impossible stray visitors—which may or may not be of casual appearance, such as *Phoca barbata*, *P. annellata*, *P. grœnlandica* and *Cystophora cristata*—we have, as constant residents in our waters, two species—the common *P. vitulina* and the larger and more local *Halichœrus griseus*—animals that differ as much in some of their habits as they do in conformation and appearance. Of the former species we need say little, but concerning the latter the several volumes of this series have given much information, making abundantly clear that it is a native of our seas and therefore a true member of our Fauna, a position that, through want of appreciation of recorded facts, had hitherto been doubtful. But our authors, in this volume at any rate, exhibit laudable caution in not advertising its haunts, leaving those who can "read between the lines" sufficient indication as to where they are, which we maintain to be a perfectly fair proceeding on the part of writers in regard to species subject to persecution. If the hairy coat of the Grey Seal approached in value that of his long-eared and furry cousins of the Southern Seas and North Pacific, the life of his race would not be worth a year's purchase, despite the dangerous character of the waters he frequents. Fortunately it is only his oil that is coveted by his would-be murderers, and that is not a sufficient inducement to them to follow him to some of the asylums he has found. We could tell of one where he feels so secure, from absence of molestation, that he will let a boat come within oar's length of him before he rolls off the rock on which he is basking—and then rather with the air of doing a courteous act in giving place to strangers who may want to land upon the shelf. All the same we fear that one of these days terrible return for his politeness will come upon him and his kindred even in the fortunate islands we have in mind, and we must not dwell longer on this subject lest we should reveal what ought to be a profound secret. But we are bound to admit that the Grey Seal is not the most intelligent animal in the world, hough his long, grave face gives him an expression of wisdom far beyond that conveyed by the chubby countenance of his commoner relative.

Of course the most important members of the Scottish fauna are at present the Red Deer and the Red Grouse—looking only to the amount of money they are the means of bringing into the country, though equally of course it is declared that the greater part of this amount, that which is paid for shooting rents, is not spent in the country. But we suppose the same might be alleged almost everywhere of rent of any kind, and heaven forefend us from dabbling in the mysteries of the "dismal science." Concerning Red Deer much more is to be told than people suppose. The statistics of Jura Forest compiled and privately printed by Mr. Henry Evans, of which an abstract is given by our authors in their Appendix (pp. 239–244) may well set any one thinking, especially as regards the death-rate, which if observed among human beings in any part of the world would set that district down as more unwholesome than any known elsewhere. The mortality is attributed chiefly to what is known as "Husk," which appears due to a "hair-like lung worm" (of what kind we cannot say), and reaches 20 *per cent.* and upwards among the *male* calves before they complete their first year, and when we consider that this is on an island with a comparatively mild climate, where every care is taken of the beasts, the result is indeed extraordinary. It is only when the zoologist is brought face to face with facts of this kind that he can realise what the Struggle for Life must be of which he has read so much, and the depth of his ignorance about it. No wonder then we cannot explain, what seems to be quite certain, the dwindling, that in many places has ended in the extinction, of the Ptarmigan. Our authors appear to attribute it to the moist influence of the Gulf Stream, but we are not conscious of any evidence that this is greater now than it was twenty, thirty or fifty years ago and surely the reason must be sought elsewhere.

We have allowed our notice of this very pleasant book to run to an excessive length, so that we must here surcease from commenting on many passages which really call for remark—most of them for praise and only a few for blame. We certainly should not care to involve ourselves in the mooted question of the alleged Pintail's nest or nests on Hysgeir off Canna (pp. 129–131); but we must protest against our authors' countenancing (p. 167, note) the often-exploded but ever reviving fallacy of Rooks' eggs being served up in place of Plovers'. The curious so-called "Tailless" or "Docked" Trouts ("club-tailed" would be a better name) of certain lochs are treated of by Dr. Traquair. They may perhaps be compared with the somewhat analogous case of the "Crummy" Stags of Jura and Mull, concerning which we are disappointed to find little or no information, which is the greater pity since the introduction of new blood has already diminished and will probably put an end to these interesting local "sports." A few words must, however, be added as to the illustrations, and especially to those from photographs by Mr. Norrie, which are not only well chosen, but for the most part extremely beautiful. The maps too are all effective if not always neat, and the little sketches "let in" to their margins are as pretty as they are accurate. Herein, as throughout the letter-press of the volume generally, the islands are most favoured, and there is only one of the plates which illustrates a scene on the Scottish mainland. So we part from Messrs. Buckley and Harvie-Brown, commending their assiduity, and wishing all success to their next venture, whether Moray or Shetland be its subject.

OUR BOOK SHELF.

Gun and Camera in Southern Africa. By H. Anderson Bryden. With numerous Illustrations and a Map. (London: Edward Stanford, 1893.)

IN this book Mr. Bryden records the incidents which happened in the course of a year of wanderings in Bechuanaland, the Kalahari Desert, and the Lake River Country, Ngamiland. The region is one in which much interest has been taken lately, and colonists and settlers will find in Mr. Bryden's lively pages exactly the sort of information that is likely to be most useful to them. The volume also includes many passages that will be read with pleasure by ethnologists, naturalists, and sportsmen. The illustrations—which are offered as "faithful delineations of places, objects, and people hitherto not often accessible to the camera"—add greatly to the value of the narrative.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Mr. H. O. Forbes's Discoveries in the Chatham Islands.

IN reply to Prof. Newton's letter, under the above title, in NATURE of last week (p. 101), in which he refers to the description by me of the Chatham Island Ralline bones under a distinct genus *Diaphorapteryx*, and observes "that one thing seems needed to make the discussion [on the probability of a land connection between the Chatham and Mascarene Islands] real, and that is the proof of the assertion that *Aphanapteryx* ever inhabited the Chatham Islands," I beg to say that in his letter there is a slight confusion of dates, which affects the question of the nomenclature. On July 29 last year I visited Cambridge for the purpose of comparing the bones from the Chatham Islands I had brought with me with the real *Aphanapteryx* remains in the Museum there. It turned out that Dr. Gadow, who was abroad, had laid them aside where Prof. Newton could not place his hand upon them, and I was, therefore, unable to see them. A week or two later, when in Edinburgh at the British Association Meeting, in a note intimating the return of Dr. Gadow, and kindly arranging for my examination of the bones, Prof. Newton adds, "I believe you will want a new generic name for what you have called *Aphanapteryx*," and suggests the name *Diaphorapteryx* instead. I was unavoidably long prevented from revisiting the Cambridge Museum, and so in describing as *Diaphorapteryx* the Chatham Island bones, at a meeting of the British Ornithologists' Club in December, 1892, I accepted the suggestion of Prof. Newton, who alone had till then seen the remains from both localities. On February 23, prior to reading my paper at the Royal Geographical Society, I again visited Cambridge, and in the most kind manner received every facility and assistance both from the Professor and from Dr. Gadow in comparing the specimens. On this occasion I was unable to recognise any sufficient characters, by which, in my estimation, to separate generically the bones from the Chatham Islands from those from Mauritius. This decision I stated at the meeting of the R.G.S. on March 13 last, and more recently in a communication to the Brit. Ornith. Club, which will appear in its forthcoming *Bulletin*. If I mistake not, however, Prof. Newton agreed with me that the Chatham Island form was nearer to *Aphanapteryx* than the latter was to *Erythromachus* of Rodriguez. Some of these remains from Mauritius have been figured by Prof. Milne-Edwards in his "Oiseaux Fossiles de France," and the remainder are fully discussed and illustrated by Dr. Gadow in a shortly-to-be-issued fasciculus of the Trans. Z.S. of London, while those from the Chatham Islands will appear shortly, I hope, in one or other of the scientific journals or Proceedings. After a careful study of all the material I have no hesitation, however, in stating meantime—as those who care will then have an opportunity of judging—that the bones from both regions are generically the same. I maintain also, that even if some osteologists should be disposed (from the somewhat larger size of the Chatham Island bones, though among them I found a number scarcely to be separated on even that ground) to make a generic distinction between them, the question would not only not fall, but I really cannot see that the argument based on their discovery in the New Zealand region would be in the least invalidated, as the forms are unquestionably so very nearly related. The importance of the distribution of the blue Waterhens, and the relationship between the Huias of New Zealand and the *Frigelupus* of Reunion—long ago pointed out by Mr. Wallace—and many other facts as far as birds are concerned recently urged by Dr. Sharpe at the Royal Institution, appears now to a fuller extent by the discovery of those unexpected forms in the Chatham Islands.

I must once more protest against the very erroneous statement that I have invoked this "tremendous hypothesis" to explain the distribution of the closely related forms of these two regions. I adduced, as I have said in my last letter, a great deal of other evidence in my paper at the Royal Geographical Society, which will appear very soon now. In addition to the facts there given I may point out the significance to this question of the results of the investigations of my lamented friend, Mr. W. A. Forbes—an anatomist of the highest acumen—on the genera *Xenicus* and *Acanthisitta* of New Zealand. He found that the affinities of the *Xenicidæ* are with the *Pipridæ* (including the *Cotingidæ*), *Tyrannidæ*, *Pittidæ*, and *Philepittidæ*—groups confined to the New Zealand, the Australian (ranging into the Oriental), the Mascarene, and the Neotropical regions, and that they have no relatives elsewhere. Nor are the following sentences from Mr. Wallace's "Geographical Distribution of Animals" without a bearing on this discussion:—"We have the pigeons and the parrots most wonderfully developed in the Australian region, which is preeminently insular, and both these groups have acquired conspicuous colours very unusual or altogether absent elsewhere. Similar colours [black and red] appear in the same two groups in the distant Mascarene islands. . . . Crests, too, are largely developed in both these groups in the Australian region only; and a crested parrot formerly lived in Mauritius—a coincidence too much like that of the colours as above noted, to be considered accidental." HENRY O. FORBES.

The Fundamental Axioms of Dynamics.

As Prof. Lodge refers in the letter published in this week's NATURE, p. 101, to my remarks on his paper on the Fundamental Axiom of Dynamics, I shall be obliged if you will allow me to state my views in your columns. Apart from all minor questions it appears to me that the main issue raised by Prof. Lodge is whether the law of the conservation of energy can be *proved* from the fundamental laws of dynamics and the assumption of contact action.

I have not the slightest objection (as he seems to suppose) to the mathematical investigation of physical facts being based on assumptions which are followed out to their logical conclusions, nor do I shrink from using such methods even when they fail in some points or lead to paradoxical conclusions. They may legitimately be accepted as convenient though imperfect mental pictures of the truth, sketches, but not finished drawings.

My objection to Prof. Lodge's "proof" is that in his attempt to avoid the unthinkable by discarding action at a distance, he adopts another equally inconceivable conception, viz. contact action.

He has already laid it down as an axiom that "material particles (atoms of matter) never come into contact." It is only by abstaining from the attempt to define the constitution of the ether that he avoids being driven to the conclusion that its various parts never come into contact either.

The assumption that he really makes is that when two bodies (including in that term both matter and the ether) act immediately upon each other, the distance between the mutually acting parts remains invariable during the action. This is not inconsistent with action at a distance. If then the phrase "contact action" be discarded the assumption of action at constant distance is a proper subject for investigation.

If the assumption be accepted the reasoning based on it is no doubt correct, but the value of the "proof" (regarded as independent or self-contained) depends entirely on the value we assign *à priori* to the fundamental assumption. I doubt whether an argument based upon it would by itself have convinced the world that the conservation of energy is a fact.

If, on the other hand, the assumption is regarded as a more or less arbitrary postulate to be justified, *à posteriori* by the fact that conclusions can be deduced from it which are otherwise known to be true, Prof. Lodge must not represent his course as the ascent of a firm ladder of argument to results which, though paradoxical, must be accepted under penalty of a *reductio ad absurdum*. On the contrary, it lies with him to justify his assumption by the use he makes of it. That the conservation of energy follows is no doubt an argument in its favour, and I for one shall look with interest for the other deductions which Prof. Lodge promises. ARTHUR W. RÜCKER.

June 2.

IF Mr. E. T. Dixon (NATURE, p. 103) will read what I have previously written on the subject of energy he will find most of his objections anticipated. I have pointed out, as he now does, that so long as potential energy is regarded solely as a "force function" the conservation of energy has no real physical meaning (pp. 532, 533. Phil. Mag., June 1881). I quite agree that potential energy belongs to a system rather than to a particle, but I do not see that the fact has any hostile significance as regards the question of *identity*.

He will also find that I have always hitherto included the connecting medium as one of the "bodies" between which actions and reactions occur. (See for instance, Phil. Mag., June 1885, pp. 483–84, and October 1879, p. 281). I do not propose to continue to do this in future, partly because I find that the word "body" is not generally or conveniently understood to mean ether as well as ordinary matter, and partly because I now realise that there is something more definite to say concerning the function of the ether as regards stress.

But Mr. Dixon seems to suppose that the denial of action at a distance means that material particles are without influence on one another until they touch; that for instance the earth cannot attract the moon unless it is in contact with it; for he says that my contention that material particles never come into contact renders nugatory the whole discussion concerning "contact action."

If this be the sort of meaning which he attaches to the phrase "action at a distance," no wonder he is unimpressed with the arguments of those who deny its prevalence in nature.

OLIVER LODGE.

MAY I make a few corrections of statements which appear in your report of Prof. Lodge's paper on the Laws of Motion (NATURE, p. 117)?

(1) I do not object to the first law on the ground of unintelligibleness, but only to the ordinary mode of enunciating it.

(2) I have not contended that Dr. Lodge's definition of energy as the name given to work done assumes conservation. On the contrary, I have expressly pointed out that it does not.

(3) I did not select the air-gun with its muzzle plugged as an instance of transference of potential energy without transformation. Prof. Lodge had cited the air-gun as an instance of the transformation of Potential Energy into kinetic during transference. I stated that if the muzzle were plugged it would serve *equally well* as an instance of the transference of potential energy without transformation. But I pointed out that both illustrations were defective and proceeded to show that in general the transformation of energy during transference is only partial.

J. G. MACGREGOR.

Hopeville, Bridge of Allan, N.B., June 5.

The Word Eudiometer.

THE following quotation from J. A. Scherer's "Geschichte der Luftgüteprüfungslehre" (Vienna, 1785), may be of interest in connection with Prof. McLeod's letter on the invention of the word "Eudiometer" (NATURE, vol. xlvii. p. 536). After referring to Fontana's Descrizione ed usi di alcuni stromenti per misurare la salubrità dell' aria" (Florence, 1775), Scherer continues (*op. cit.*, vol. i. p. 153), "Bald nach der Herausgabe der gedachten Instrumente machte Hr. Landriani ein neues bekannt, der erste, der es Eudiometer nannte. Er versichert uns er habe seinen Luftgütemesser von Abt Fontana nicht entlehnt. Daher gehört die Ehre der Reformation des Priestley'schen Instruments Hrn. Landriani, die ihm auch Fontana selbst in zwei Briefen einräumt."

Landriani's own statement quoted by Prof. McLeod is thus fully confirmed by contemporary authority. Scherer's book, which has just been purchased for the Owens College from the Kopp library, is full of interesting historical information with regard to eudiometry.

PHILIP J. HARTOG.

Owens College, May 23.

Singular Swarms of Flies.

MR. FROUDE's letter (p. 103) forcibly reminds me of a swarm of flies which overlaid every one who was on the parade at Ventnor, and drove numbers off the pier on the forenoon of a day which certainly fell on or between May 13 and 16, 1891. My diary bears only witness to the fact that I was then at Ventnor, but I shall never forget that as I went towards the black clouds I met a venerable friend, whose white hair, beard, and light coat were literally blackened with flies. The natives, who had had previous experience of such a cloud, ascribed it to the "mackerel fly." My colleagues in the entomological department of the British Museum told me I had witnessed a flight of *Bibio Marci* (St. Mark's fly), and, on reading up the subject, I found no reason to doubt that they had made an accurate diagnosis of a slightly and imperfectly told story.

I have a definite recollection of the flies' rapid disappearance, and I have very little doubt that Mr. Froude has been the witness of a cloud of the same dipterous insect.

F. JEFFREY BELL.

5, Radnor Place, Gloucester Square, W., June 2.

P.S.—The weather was very warm during the days mentioned, but the succeeding (Whit) Monday was marked by a fall of snow in several parts of England. *Absit omen!* I add this as I note that Mr. Froude suggests that the special character of the swarms may have some relation to "some condition of the atmosphere."

THE phenomenon so well and exactly described by your correspondent, Mr. R. E. Froude (NATURE, vol. xlviii. p. 103) was seen the same day and hour—that is, between 1 and 1.30, May 27—at Parkstone, near Poole, Dorset. A party which had driven over from my house, and lunched at the Harbour Hotel, saw every tree-top crowned, as it were, with a smoke-like column of flies, every column with the same slant one way, described by Mr. Froude, only it was not noticed that this was towards the sun. The strange sight was described to me by my daughter, by word and pencil, last Saturday, immediately on reaching home, and confirmed by her companions.

HENRY CECIL.

Bregner, Bournemouth, June 3.

THE ANNUAL VISITATION OF THE GREENWICH OBSERVATORY.

AT the Annual Visitation of this Observatory, which took place on Saturday, June 3 last, the Astronomer Royal presented his report to the Board of Visitors.

The present want of accommodation is felt in all the departments of the Observatory, a number of the staff being at present housed in the Octagon room, which forms part of the Astronomer Royal's official residence. The Admiralty have now authorised the completion of the central octagon by the addition of a story and the erection of the Lassell dome over it.

In place of the old cylindrical dome on the south-east tower, which was dismounted in November last, the new 36-foot dome was erected at the beginning of the year, the work of construction and erection being completed most satisfactorily by Messrs. T. Cooke and Sons.

The electric light installation for the principal instruments proposed last year has been sanctioned, and the necessary generating plant, consisting of gas-engine, dynamo, accumulators, and main leads, has been supplied. It is proposed to set these up on the ground floor of the new south wing.

Referring now to the astronomical observations, the work of observing the sun, moon, planets, and fundamental stars with the transit circle has been considerably increased, owing to the extraordinarily fine weather in the months of March and April, the number of observations being the largest ever recorded. The numerical statement is as follows:—

Transits, the separate limbs being counted as separate observations	8217
Determinations of collimation error ...	304
Determinations of level error	512
Circle observations	7179
Determinations of nadir point (included in the number of circle observations)... ...	461
Reflexion observations of stars (similarly included)	527

The annual catalogue of stars observed in 1892 contains 1710 stars.

The report goes on to say:—

As an illustration of the continuity of fine weather in March and April, it may be mentioned that 2600 transits and 2300 circle observations were made in these two months, the average corresponding numbers for the seven previous years being 945 and 877 respectively; that 70 observations of upper and lower culminations of Polaris were obtained (exclusive of isolated observations, which are only used for azimuth error and not for place of the star), the average for these months in ten years preceding being 22·2, and the greatest in any of these years 38 (in 1885), and that 24 groups of clock stars, extending over more than twelve hours, were obtained, the mean for ten years preceding in March and April being 2·6. In the last case something must be attributed to the special interest shown by the observers recently in obtaining long groups of clock stars.

The apparent correction for discordance between the nadir observations and stars observed by reflexion for 1892 is 0″·25, and has been persistently negative for some months. An investigation of the screws of the microscopes used showed that several of them are the worse for wear.

From the observations of 1892 the west latitude of the transit circle was found to be 38° 31′ 22″·10, a value differing by + 0″·20 from that adopted. Recent investigations have made it probable that the co-latitude undergoes fluctuations of short period: and in comparing the observations in the individual years 1877–86 with the final results in the Ten Year Catalogue, confirmatory evidence of these fluctuations was found. Mr. Thackeray was thus led to undertake an examination of all the observations of N.P.D. of the four close circumpolar stars since 1851. The results were found to accord well with Mr. S. C. Chandler's hypothesis (*Astronomical Journal*, No. 277), and have been communicated to the Royal Astronomical Society (vide *Monthly Notices*, liii. p. 3).

The correction to tabular obliquity of the ecliptic from solar observations in 1892 is + 0″·44, which is rather a large quantity. The discordance between the results from the summer and winter solstices is + 0″·40, indicating that the mean of the observed distances from the pole to the ecliptic is too small by + 0″·20, and thus confirming the stellar observations for co-latitude.

Computing the value from Hansen's lunar tables, the mean error of the moon's tabular place was found to be + 0·083s. in R.A. and + 1″·29 in longitude, as deduced from ninety-five observations in 1892; this agrees well with the results obtained in 1891. The mean value of these quantities for the ten years 1883–92 are + 0·044s. and + 0″·61. The mean error of the moon in N.P.D. for 1892 was − 0″·27.

Owing to great pressure of longitude and other work, the work with the altazimuth was suspended from May to October 18, 1892, the number of observations falling below that usually recorded. The total number in the year ending May 10, 1892, is—

Azimuth of the Moon and Stars	167
,, ,, Mark I.	62
,, ,, Mark II.	64
Zenith distances of the Moon...	62
,, ,, ,, Mark I.	60
,, ,, ,, Mark II.	62

The provision of the new universal transit-circle to replace the existing altazimuth, and to serve as a duplicate meridian instrument for fundamental determinations, with suitable building and dome, having been sanctioned by the Government, its construction has been entrusted to Messrs. Troughton and Simms, who are now preparing the working drawings. This instrument will be erected to the north of the Magnetic Observatory. Some difficulty seems to have occurred with regard to the siderial standard clock, which on June 26 was found to have stopped. An examination soon showed that the oil on the escape pivots had thickened. At the beginning of this year the maintaining power was strengthened, and the barometric inequality adjusted.

Owing to the fact of the new dome only being recently completed, the tube of the 28-inch refractor, together with the declination axis cones, declination circle, and clamping circle are not yet in place. The object glass is at the Observatory, and ready for mounting.

Last May the Merz refractor (12¾ inch) of the south-east equatorial was mounted in place of the Lassell 2-feet reflector, the same mounting carrying the Thompson 9-inch photographic telescope.

Since February Mr. Lewis has used this instrument for double-star work, and he has made 545 measures of position angle, and 609 of distance of 85 pairs; 32 pairs being less than 1″ apart, 26 between 1″ and 2″, 8 between 2″ and 3″, and 19 over 3″.

With regard to occultations, 26 disappearances and 7 reappearances of stars by the moon have been observed, including 7 disappearances and 3 reappearances observed during the lunar eclipse of May 11, 1892, and 10 disappearances of stars below the *Nautical Almanac* limit of brightness (6·5), approximately predicted by Mr. Crommelin. Disappearance of Uranus behind the Moon on July 3, an occultation of 73 Piscium by Jupiter on May 23, and 62 phenomena of Jupiter's satellites were also observed. All these observations are completely reduced to February 26, 1893.

Among other miscellaneous observations made may be mentioned:—Observations of comets, differences of R.A. and N.P.D. of Saturn and γ Virginis, on the occasion of their conjunction; and of Mars and Ceres at the time of their conjunction, &c.

With the Astrographic equatorial 722 plates, with a total of 1812 exposures, have been taken on 161 nights in the year ending May 10, and of these 116 have been rejected, viz. 57 from photographic defects, 6 from mechanical injury, 12 from mistakes in setting, 6 from the plate being wrongly placed in the carrier, 7 from failure in clock driving, and 28 from interference by cloud. The following statement shows the progress made with the photographic mapping of the heavens in the year, May 11, 1892, to May 10, 1893:—

	No. of Photos taken.	Successful Plates.
Astrographic Chart (exposure 40m.) ...	200	183
Plates for Catalogue (exposures 6m., 3m., and 20s.)...	367	288
Number of Fields photographed for the Chart	—	172
Number of Fields photographed for the Catalogue	—	271
Total number of Fields photographed since the commencement of the work for the Chart	—	176
Total Number of Fields photographed since the commencement of the work for the Catalogue	—	299

It has been made a practice to take a trail on each night on a catalogue plate as a check on the orientation, and during the past year 127 plates with trails have been thus secured.

With the same instrument, and included in the 722 mentioned above, were taken photographs of Nova Aurigæ (49), for zero of scales and orientation (36), lunar eclipse, May 11 (4), Comet Holmes (2), Saturn (5), conjunction of Saturn and γ Virginis (16), &c.

Experimental plates of Jupiter, Saturn, double stars, &c., have also been taken with the image enlarged about fourteen times by a secondary magnifier, consisting of a triple cemented concave lens of 1⅝ inches diameter, and 3 inches focus, supplied by Mr. T. R. Dallmeyer. The results, as the report states, are very promising.

No spectroscopic observations have been made during the past year, the regular observations for stellar motion in the line of sight having been interrupted by the dismounting of the south-east equatorial, and there being great pressure in the solar photographic work. The telescope and camera of the Dallmeyer photoheliograph were again removed on September 9, 1892, from the wooden dome, where the new buildings obscured the horizon, to the first floor of the new museum, where they were re-mounted on stand No. 3, which was simply placed on the floor and found sufficiently steady. From this position it was possible to photograph the sun during about two hours each day.

In the year ending May 10, 1893, photographs of the sun have been taken with this instrument on 180 days, and of these 410 have been selected for preservation, besides twenty-two photographs with double images of the sun for determination of zero of position.

The photographic telescope has been in regular use as a photoheliograph since January, 1893, and photographs of the sun have been obtained with it on eighty-nine days, of which 158 have been selected for preservation. In all, with one photoheliograph or the other, a record of the state of the solar surface has been secured on 220 days during the year. A new enlarging lens by Messrs. Ross and Co., which appears to be very free from distortion, was fitted to the Thompson photoheliograph on December 13, and has been used regularly for the eight-inch photographs of the sun. Taking into account the India and Mauritius photographs received from the Solar Physics Committee, solar pictures for 362 out of 366 days are available for measurement. The photographs show that solar activity has throughout the past year been fully maintained, the mean daily spotted area for the years 1890, 1891, 1892, being 100, 566, and 1230 respectively.

The great solar activity mentioned above has its reaction also in the number of computers employed, for the report says that to cope with this unexpectedly severe sun-spot maximum it has been necessary to largely increase the number of computers employed on this work, and a further addition will probably be required, if, as seems likely, the solar activity continues to increase.

With regard to the magnetic observations, the registration has been carried on as in former years, the new photographic processes recording with clearness and delicacy many rapid magnetic movements that occur during magnetic storms.

The disturbance of the earth current registers due to the trains running on the City and South London Electric Railway still continues, and is of about the same magnitude as before. The substitution of a non-magnetic silver pointer for the upper magnetic needle in the galvanometers for the earth current apparatus, as mentioned in the last report, has proved very successful, the scale values, which used to vary considerably, having since remained remarkably constant.

In view of the approaching introduction of a dynamo into the Observatory grounds for electric lighting, experiments have been made to determine the possible effect on the magnetographs of the dynamo unshielded and with triple iron shield. These experiments were carried out at Messrs. Johnson and Phillips's factory, Charlton, the deflection of the declination magnet of the portable unifilar magnetometer being observed at distances of 20 and 40 feet respectively due west (magnetic) of the dynamo, the poles of which were in the east and west direction (magnetic), thus giving the maximum deflecting effect. At the Royal Observatory the poles of the dynamo will be north and south (astronomical), and it will be placed at a distance of about 170 feet from the magnets and nearly due south (magnetic). Making due allowance for this, the experiments at Charlton would give the following results:—

Effect on	Declination Magnet	or	Horizontal Force Magnet.
Dynamo unshielded	4″		·00008
Dynamo with triple shield ...	0″·5		·00001

the effect on the horizontal force magnet being expressed in parts of the whole horizontal force. The corresponding displacements of the magnetograph registers would be only 1/200th of an inch for declination and 1/400th of an inch for horizontal force, in each case with triple shield to the dynamo.

The following are the principal results for the magnetic elements for 1892:—

Mean declination (approximate)	17° 18′ west	
Mean horizontal force ...	3·9613	(in British units)
	1·8265	(in metric units)
Mean dip	67° 18′ 42″	(by 9-inch needles)
	67° 19′ 45″	(by 6-inch needles)
	67° 21′ 7″	(by 3-inch needles)

Meteorological observations have been continuously maintained during the past year, and the reductions are in the following state:—

The observations of barometer, thermometers, anemometers, rain-gauges, and sunshine-recorder (corrected, where necessary, for instrumental error) are reduced up to the present time. On the photographic sheets all the time-scales are laid down, and the hourly ordinates are read out for the dry and wet bulb thermometers to the end of the year 1892, and for electrometer to the end of July 1892. The table of principal changes in the direction of the wind for 1892 is complete.

The mean temperature of the year 1892 was 48°·1, being 1°·4 below the average of the 50 years, 1841–1890. The highest air temperature in the shade was 85°·9 on June 10, and the lowest 17°·6 on December 27. The mean monthly temperature in 1892 was below the average in all months excepting May, August, and November. In March it was below the average by 4°·4, in October by 4°·6, and in December by 3°·0.

The mean daily motion of the air in 1892 was 265 miles, being 17 miles below the average of the preceding 25 years. The greatest daily motion was 687 miles on January 29, and the least, 48 miles on December 28. The greatest pressure registered was 11·8 lbs. on the square foot on October 9.

Bright sunshine was recorded on 1277 hours during the year, this being 7 hours below the average of the preceding 15 years. The sun being above the horizon for 4465 hours, the mean proportion of sunshine for the year was 0·286, constant sunshine being represented by unity.

The rainfall amounted to 22·3 inches in 1892, this being 2·2 inches below the average of the fifty years 1841-1890.

In the determination of the longitude of Paris, four observers, two French and two English, took part in the work, as in 1888; three of them were the same as before (Colonel Bassot, Commandant Defforges, and Mr. Turner), but Mr. Hollis replaced Mr. Lewis, whose special attention was required in the Time department. The plan of operations adopted in 1888 was only modified in the following particulars: two clocks were used instead of one, at each end of the line, and all the clocks were placed in rooms kept at nearly constant temperature. The Sidereal Standard was used by the English observer at Greenwich throughout. The English observers used the small chronographs procured for the Montreal longitude, with one pen only, thus avoiding the troublesome correction for parallax of pens.

In the Astronomer Royal's general remarks, he mentions that "the work of the Observatory during the past year has been carried on under circumstances of exceptional difficulty. In the first place the operations for the determination of the longitudes of Paris and Montreal involved the absence of the Chief Assistant and of another assistant for protracted periods during last summer and autumn. Secondly, for six months the Observatory was left entirely without the services of a clerk, and the appointment of a permanent officer to undertake cash and other clerical duties has not yet been made; thus the scientific work of the Observatory has seriously suffered in consequence. It has not been possible for me, while harassed with constant interruptions on matters of administrative detail, to carry out the scientific investigations connected with the Observatory, which properly fall within the province of the Astronomer Royal. Thus, during the past year, I have had repeatedly to lay aside the important subject of the measurement of the plates of the astrographic chart in order to deal with details of cash accounts and other similar matters, which properly pertain to the functions of a clerk. In this connection I may mention that some years ago I proposed a photographic corrector, which, at a comparatively small cost, would render an ordinary astronomical refracting telescope available for photography; but, though a trial instrument has been made, and though I have partly worked out the details of a more complete form, I have never been able to command sufficient leisure, tolerably free from interruptions, to enable me to complete the rather troublesome optical calculations. Such a corrector could be usefully applied to the new 28-inch telescope as well as to other large instruments; but under present conditions I fear that there is little prospect of my being in a position to work out the idea."

"The growth of the Observatory buildings, involving the introduction of large masses of iron, raises the question of the possible disturbing effect on the magnets in their present position. Though the masses of iron would be at such a distance that they could not sensibly affect the registers of magnetic changes, which are purely differential, it is possible that the aggregate effect on the absolute determinations of the magnetic elements might become appreciable. Under these circumstances it is desirable that an auxiliary magnetic station for determination of absolute values of the magnetic elements should be established in the immediate neighbourhood of the Observatory, at such a distance that there would be no suspicion of disturbance from the iron in the buildings." W. J. S. L.

REV. CHARLES PRITCHARD, D.D., F.R.S.

ANOTHER and a familiar figure has passed from among us, diminishing the strength of the tie that links the present generation to the science of the past. Almost a contemporary of Airy and of Herschel at Cambridge, Prof. Pritchard has seen the school, which they may be said to have inaugurated, lose its members one after another, to be himself among the last. But in no sense can it be said that he outlived his reputation, or that he was not a worthy disciple and an admirable exponent of that school. Nor was he content to remain simply a disciple. His ambition was to stand in the front rank, and to contribute his quota to the further progress of science. And this is the more remarkable and the more praiseworthy when it is remembered that he was considerably advanced in life before he devoted himself to any special science.

For Prof. Pritchard's early life had been spent, and worthily spent, in an endeavour to exhibit an improved method of education in the then upper middle-class schools. Of the success that attended his efforts, one of his old pupils, the present Dean of Westminster, has recently given an appreciative account. Dean Bradley has contrasted the dull methods that prevailed generally some sixty years since, even in schools of repute, with the vigour and enthusiasm which characterised the newer teaching, whose importance Prof. Pritchard early recognised and enforced. For thirty years he led the life of an active schoolmaster, and that he was successful in his vocation is fully established by the long list of the names of his pupils, famous in every walk of life. For private and personal reasons he retired from this career, and then his ambition was to take active clerical duty in some country parish. But in this he was disappointed, for as he has told the writer of this notice more than once, that though he was a divine in mind and heart, he was made an astronomer by Providence. But his loyal attachment to the Church of England and his scientific training placed him frequently in a position to render services to both science and religion. This is shown by the thoughtful and eloquent sermons that he has frequently preached on the occasions of the meeting of the British Association, as well as by his Hulsean Lectures at Cambridge, or in the capacity of Select Preacher at Oxford.

In 1870 the Savilian Professorship of Astronomy in Oxford fell vacant through the decease of Prof. Donkin. At the urgent recommendation of Sir John Herschel, Lord Hatherley, who was at the time Lord Chancellor, was induced to exercise his influence among the trustees of the Savilian estates, and Prof. Pritchard was elected to the vacant chair. How worthily he filled this office is known to the readers of this journal. It is sufficient to recal that he induced the University, shortly after his appointment, to supply an astronomical observatory, for at this date there was no observatory under academical control, and not only was research impossible, but very inadequate provision was made for the teaching of his class. The modest establishment originally contemplated by the University was materially increased by the munificence of the late Dr. De la Rue, in a way which admirably supplemented the judicious expenditure of the University. In later time a lecture-room and library had to be provided, and Prof. Pritchard probably felt that in the possession of a small, but tolerably complete, observatory, he gained rather than lost, from the fact that it was called into existence in quite modern times. Here it was his good fortune early to recognise the important part that photography was destined to play in the new astronomy, and before the gelatine plate had thoroughly revolutionised the art, he was at work on bright objects like the moon, to which photographic methods could then be applied. His success justified his foresight, and though in his subsequent career he frequently turned aside to pursue other lines of inquiry, he always returned to his original plan of investigation by means of photography.

In one of these excursions into more varied inquiries he was tempted to investigate the magnitude of the brighter stars on a plan which had occurred to him while at Clapham, and was, I believe, the practical outcome of a suggestion of the Rev. W. R. Dawes. This was the process of extinction by means of a wedge of neutral-tinted glass, used differentially. The method was carried out practically with great success, and the results of his work, embodied in a *Uranometria Nova Oxoniensis* received the reward of the medal of the Royal Astronomical Society, and procured for him, what he valued quite as highly, an honorary fellowship from his old college of Saint John's, at Cambridge. To secure the necessary completeness in this inquiry, Prof. Pritchard undertook to visit Egypt to determine the amount of atmospheric absorption. It was a source of great gratification to him to know that the more protracted inquiry of Dr. Müller led to practically the same result, and confirmed his investigation in every material particular.

Another of his researches, but one which he always held to be incomplete, was an effort to determine the relative co-ordinates of the stars of the Pleiades with a view to ascertaining the mutual proper motions. This group of stars had for him a great fascination, and to within a few days of his death he was at work endeavouring to supplement this inquiry by photographic methods. His favourite motto was—

> spem nos vetat inchoare longam
> aetas,

but certainly he never acted by the implied caution. To undertake some fresh work as soon as, or before the last was finished was his constant aim, and his zeal was generally equalled by his success. He undertook very little from which he did not get some positive result, for his method was to work tentatively, and to relinquish the inquiry if it did not appear promising. In this way he took up what he regarded as the greatest work of his life, the determination of the parallax of stars of the second magnitude. In this investigation he showed the keenest interest, and much of the work was performed not only under his directions, but actually by himself, and the Royal Society, recognising the importance of this work, and also Prof. Pritchard's earnest and protracted devotion to astronomy, awarded him the Royal Medal last year. W. E. P.

NOTES.

THE annual meeting of the Royal Society for the election of Fellows was held in their apartments at Burlington House on Thursday last, when the following gentlemen were elected into the Society:—Prof. William Burnside, Prof. Wyndham R. Dunstan, William Ellis, Prof. J. Cossar Ewart, Prof. William Tennant Gairdner, Ernest William Hobson, Sir Henry Hoyle Howorth, Edwin Tulley Newton, Charles Scott Sherrington, Edward C. Stirling, John Isaac Thornycroft, Prof. James William H. Trail, Alfred Russel Wallace, Prof. Arthur Mason Worthington, Prof. Sydney Young.

AMONG Fellows of the Royal Society whose names appear in the list of birthday honours are Dr. B. W. Richardson, F.R.S., Capt. A. Noble, C.B., F.R.S., and Mr. Charles Todd, C.M.G., F.R.S. Dr. Richardson, who has been knighted, is well-known as a writer on hygienic and medical subjects, and Capt. Noble, who is created a Knight Commander of the Bath, is an authority on explosives. Mr. Todd has been promoted to Knight Commander of the Order of St. Michael and St. George. In the announcement of the honour that has been conferred upon him, he is described as Postmaster-General and Superintendent of Telegraphs of the colony of South Australia. It should be pointed out, however, that Mr. Todd is also the Government Astronomer at Adelaide and that he has published numerous contributions to meteorology and astronomy. It almost appears as if Mr. Todd's standing as an astronomer and man of science has been wilfully avoided, for we can hardly think that the Colonial Office is in blissful ignorance of his scientific work. The only scientific man in Government employ whose services have been recognised is Mr. David Morris, the assistant director of the Botanic Gardens at Kew, who has been made a Companion of the Order of St. Michael and St. George.

THE ladies' *conversazione* of the Royal Society was held last night in the Society's apartments at Burlington House.

THE President of the Society of Antiquaries has issued invitations for a *conversazione* at Burlington House, on the 14th instant.

IT is expected that, at the meeting of the Royal Astronomical Society to-morrow evening, Prof. Thorpe and Mr. Alfred Taylor will give an account of the expeditions to observe the recent total solar eclipse. Prof. E. E. Barnard, of the Lick Observatory, will also be present, and will address the meeting.

THE annual *conversazione* of the Society of Arts will take place at the Imperial Institute, South Kensington, on Friday, June 30, from 9 to 12 p.m.

ON June 26, 1793, died Gilbert White of Selborne, a man who has done perhaps more than any other of his countrymen to awaken a taste for natural history and encourage its pursuit. A writer in the June number of *The Zoologist* gives a sketch of the life of this naturalist, and points out that now is the time to erect some kind of monument to his memory. The sole memorial which at present exists is a marble tablet on the chancel wall of the church in which he officiated. This is not as it should be. A marble bust was erected to Richard Jefferies, in Winchester Cathedral, a few months after his death, while Gilbert White, also a Hampshire man, has remained unhonoured for a century. As to the claim of the author of the "Natural History of Selborne," to a memorial there can be no doubt, and it is to be hoped that a committee will be formed to take the matter in hand, and carry it to a successful termination. Unfortunately no portrait of Gilbert White is in existence, so there is a difficulty in designing a monument with a statue unless it be decided to allow the sculptor to carve the features from his imagination. Under these circumstances, the preferable plan would be to erect a monument emblematical of the avocation of a naturalist, such, for example, as the monument to the naturalist, John James Audubon, which was unveiled at New York on April 26 last. Whether the monument should be erected at the little village of Selborne, or in the borough-town of Petersfield, ought soon to be decided. We trust that when an appeal for funds is made, there will be a hearty response to it.

WE regret to have to record the death of Dr. Carl Semper, Professor of Zoology and Comparative Anatomy in the University of Würzburg, on May 29.

IT has been resolved by the Government of India that in the future two-thirds of the officers of the Geological Survey shall be primarily engaged in the explorations necessary for the completion of the geological map, and the remaining third on the investigation of mineral fields. According to the *Times*, the exploration in the latter case will be confined to such preliminary examination as may be necessary to supply general information regarding their character and extent to capitalists and promoters, upon whom will rest the responsibility for more detailed prospecting.

AN International Electrical Congress will be held in connection with the Columbian Exposition, at Chicago, in August. There will be three sections, one dealing with pure theory, another with theory and practice, and a third with practice only. Papers are solicited upon electrical subjects, and should be sent to Prof. T. C. Mendenhall, Washington, D.C., not later than August 1. Electrical standards and units will be considered by a body consisting of those specially designated as representative delegates from the various Governments.

THE second meeting of the International Maritime Congress is to be held in the rooms of the Institution of Civil Engineers next month. The chief object of the congress is the reading and discussion of papers on matters relating to the promotion and security of maritime traffic and commerce. After the meeting it is proposed to visit the docks along the Thames, and some of the provincial seaports.

THE annual general meeting of the Institution of Civil Engineers was held on May 30. Before proceeding to the ordinary business, H.R.H. the Duke of York was elected an honorary member. The ballot for Council resulted in the election of Mr. Alfred Giles as President; of Sir Robert Rawlinson, Sir B. Baker, Sir Jas. N. Douglass, and Mr. J. W. Barry, as Vice-Presidents; and of Dr. W. Anderson, Mr. A. R. Binnie, Sir Douglas Fox, Sir Chas. A. Hartley, Messrs. J. C. Hawkshaw, C. Hawksley, Alex. B. W. Kennedy, Sir Bradford Leslie, Mr. J. Mansergh, Sir Guilford Molesworth, Mr. W. H. Preece, Sir E. J. Reed, Messrs. W. Shelford, F. W. Webb, and W. H. White as other Members of Council.

THE weather during the latter part of last week continued particularly dry over the greater part of these islands, owing to an anticyclone which lay over the Atlantic embracing most part of the country, but shallow depressions ormed over Scandinavia and the Baltic, and under their influence some slight showers occurred in the extreme north and north-west. At the end of the week however the anticyclone temporarily shifted somewhat southwards and eastwards, thunderstorms became prevalent in the north, east, and south-east, and rain fell at most stations, amounting to over half an inch in the north-east of Scotland, but generally speaking the amounts were slight elsewhere; on Tuesday, the 6th inst., the anticyclone again embraced the whole of the southern portion of our islands. During the first part of the period frost occurred on the ground in many parts of England; and although the maximum temperatures have not been high generally, they have at times exceeded 70° in different parts of Great Britain, but in the extreme north the highest readings have generally been below 60°. The *Weekly Weather Report* of the 3rd inst. showed that the temperature was slightly below the average in some of the wheat-producing districts, and rather above it in the grazing districts. Rainfall was below the mean everywhere; the deficiency since the beginning of the year ranged from 2·3 inches in the north of Scotland to 6·0 inches in the west of Scotland. Bright sunshine was only above the average in the west of Scotland, the south-west of England, and the Channel Islands. In the latter district the duration was as high as 70 per cent. of the possible amount.

THE Meteorological Council have issued the fourth volume of Hourly Means of the readings obtained from the self-recording instruments at their observatories for the year 1890. The tables contain hourly means or totals for periods of five days, months, and for the year, and, with the exception of the wind observations, daily values are also given. Breaks in the hourly readings are rare, but occur at times from failure of photography, stoppage of clocks, and in the case of the wet-bulb thermometer, owing to frost; such cases, however, are carefully examined and the losses can usually be made good by interpolation, with a very near approach to accuracy.

SIR C. TODD has published the meteorological observations made at the Adelaide Observatory and other places in the colony during the year 1890. The maximum shade temperature at Adelaide was 105° on January 18, and the minimum 34°·2 on July 17; the greatest range in 24 hours was 38°·8 on January 4th, and the lowest temperature on grass was 25° on July 17. Throughout the colony generally very oppressive weather was experienced in January and February, with heavy tropical rains over northern areas, and the winter also was very wet. The extraordinary rainfall (especially in the first three months) was the chief feature of the year, which was the wettest on record, some stations having a fall of over 100 inches.

A CORRESPONDENT calls our attention to a peculiar phenomenon witnessed at Aboyne on the morning of May 26. "Stretching along the falls of Morven and Culblean, and slightly below the top of the former, was a magnificent ribbon, exhibiting the full spectrum of colours from red to violet—in fact, a perfect 'rainbow,' but without the slightest curve. The sun was shining brightly in the east, while it was raining on Morven, which, of course, accounts for the colours; but I am unable to account for the absence of the arch." The lowest part of the ribbon showed the least refrangible colours.

A NUMBER of experiments to determine the temperature of the steam arising from a boiling salt solution have been made from time to time, but the conclusions have frequently been of a conicting character. The difficulty of arriving at trustworthy results lies in the fact that the walls of the steam-chamber must be above 100° C., and yet below the temperature of the solution, and that, at the same time, a sufficient quantity of steam must escape from the solution to ensure that these walls shall have no material cooling effect upon the steam. These desiderata are all met by an arrangement employed by Prof. Sakurai, and described in the Journal of the College of Science, Imperial University, Japan, vol. vi., part i. From experiments on solutions of calcium chloride, sodium nitrate, and potassium nitrate, it appears that the temperature of the steam escaping from a boiling solution is exactly the same as that of the solution itself.

To measure the viscosity of liquids they are let flow, under given conditions of pressure and temperature, through a capillary tube, and the time of passage is determined. This is rather unsuitable for very viscous liquids, such as concentrated glycerine; and Herr Brodmann has devised a method (*Wied. Ann.*) for determining co-efficients of friction, where these exceed a thousand times that of water. The liquid flows by gravity through a vertical tube from a wide vessel above, filled to a certain height, into a small shallow vessel below, standing on one scale of a chemical balance, the other scale being weighted so that it is down. A time comes when this preponderance ceases. The moment of passage of a certain mark is noted, a weight is added to the weight-scale, and the process is repeated. The difference of time between two of these passages corresponds, after some corrections, to the direction of outflow of a quantity of liquid equal in mass to the added weight.

A NOTE in *Électricité* gives the substance of a letter to the Génie Civil, in which the correspondent shows that there is a difference of potential between the water and gas pipes in all houses, and that if one terminal of a telephone is joined, say, to the water-pipe, on lightly touching the gas-pipe with the other, a crackling sound is heard in the telephone indicating the passage of a current. By replacing the telephone by a galvanometer, it is found that the negative pole is formed by the gas-pipe, and that the galvanometer deflection is permanent and constant in amount during several months, though there is a slight diurnal variation. The author attributes these currents to a slow chemical change in the pipes, which thus form the plates of a battery. However, these observations suggested that the pipes must be fairly well insulated from each other, and might act as conductors for telephonic communication, and he has succeeded in carrying on a conversation, without any other connecting conductor between two houses at a distance of a hundred metres apart. In this experiment the microphone, without any induction coil, was joined to three bichromate cells. It is very easy to see if the experiment will succeed, as it is only necessary to set a small induction coil to work, joining its terminals to the water and gas-pipes, then in all neighbouring houses in which, on joining a telephone to the pipes, the sound of the coil is heard communication is good. Even if speech cannot be satisfactorily transmitted, it would be possible to communicate by the ordinary Morse signals.

A HIGHLY sensitive manometer, suitable for measuring small variations of high pressures, is described by M. Villard in No. 21 of the *Comptes Rendus*. It consists of a U-tube one or two mm. in diameter and about 20 cm. long, one end of which leads into a closed glass cylinder about 50 sq. mm. in section and 8 or 10 cm. long or longer, according to the degree of sensibility required. The other end opens into another wide tube ending in a narrower portion, which may be bent back. A narrow copper tube fixed inside this portion by about 3 cm. of marine glue forms a most efficient mouthpiece and offers an almost indefinitely large resistance to the passage of gaseous matter. Enough mercury is contained in the U-tube to fill one of its branches. The filling is to a great extent self-acting. The mouthpiece need only be connected to a compressed gas reservoir. The gas bubbles up through the narrow tube and fills the cylinder at the pressure required. A slight expansion subsequently enables the mercury to reenter the narrow tube, and the position of the thread of mercury is then read off on a scale. In one of the instruments constructed, which has a reservoir of 5 cc. capacity, a change of level of 1 mm. at 20 atmospheres corresponds to a change of pressure amounting to 1 in 2500, so that it may safely be said that at 50 atmospheres the same change of level indicates a change in pressure of one-fiftieth of an atmosphere. But this amount of sensitiveness may be increased by making the reservoir longer, and since it is possible to take readings to 0·1 mm., the instrument may be said to indicate differences as small as 1 in 25,000. The variation in height of the mercury must of course be allowed for, and the tube and reservoir accurately gauged before the instrument is set up. After use at a high pressure it can be opened to the air, when the compressed gas will escape in bubbles through the wide tube. It is found that the instrument is easily made strong enough to work with safety at 100 atmospheres.

A REPORT on "The Hawks and Owls of the United States," with special reference to the economic status of the various species, has been prepared by Dr. A. K. Fisher for the U.S. Department of Agriculture. Of the seventy-three species and sub-species described only six prove to be injurious, and three of those are extremely rare. The contents of about 2700 stomachs of hawks and owls were examined, and omitting the six species that feed largely on poultry and game, 56 per cent. contained mice and other small mammals, 27 per cent. insects, and only $3\frac{1}{2}$ per cent. poultry or game birds. This result shows that a class of birds commonly looked upon as enemies to the farmer really rank among his best friends. The report contains twenty-five coloured plates.

AT a meeting of the Norfolk and Norwich Naturalists' Society, held on May 30, a resolution with regard to the Wild Birds Protection Bill now before the House of Lords was unanimously passed, and the president requested to forward the same to the Earl of Kimberley, one of the Vice-presidents, asking his cooperation with its objects. The result of the proposed amendments would be that the County Council should be empowered to order the protection of certain specified districts easily defined, rather than the eggs of specified species, which, in many instances, so closely resemble those of other species (as for instance, those of the Teal and Gargany Teal, and the Ruff and Redshank) that their identification would be so difficult to establish as to render a conviction practically impossible.

IN the fourth annual report of the Missouri Botanical Garden, which has just been published, Mr. W. Trelease gives the results of further studies of yuccas and their pollination. Mr. Albert S. Hitchcock also contributes a description of plants collected in the Bahamas, Jamaica, and Grand Cayman.

MESSRS. BLACKIE AND SON have added another to their already large number of science text-books. "Chemistry for All," by W. Jerome Harrison and R. J. Bailey, is a tersely-written account of the chemistry of common things, in which equations, formulæ, chemical symbols, and arithmetical calculations are eschewed. There is little new in the book, either in the text or illustrations.

MESSRS. MACMILLAN AND CO. have just published a fine work by Mr. G. W. Caldwell Hutchinson, entitled "Some Hints on Learning to Draw." A few excellent, though brief, remarks on elementary anatomy precede the description of drawing the human figure, but artists do not yet seem to realise the equal importance of knowing something about the elements of physical science before conceiving pictures of natural phenomena.

MESSRS. GAUTHIER-VILLARS have issued two small volumes by M. P. Minel on "L'Electricité Industrielle." One deals with potential lines of force and electro-magnetic units, and in the other, magnetic circuits and induction machines are considered. The object of the author has been to bring together the theoretical principles necessary to the proper understanding of dynamo-electric machinery and electric lighting.

A USEFUL little book by M. Henri Coupin on "L'Aquarium d'Eau Douce" has recently been published by Messrs. Baillière. It is well illustrated, and should be interesting to young naturalists. The author describes how to capture, preserve, and study some of the common types of plants and animals found in fresh water.

A TRANSLATION of Dr. Migula's "Introduction to Practical Bacteriology," by M. and H. J. Campbell, has just been published by Messrs. Swan Sonnenschein and Co. The German edition was reviewed in these columns on June 30, 1892.

THE Geological and Natural History Survey of Minnesota have issued their twentieth annual report. Among other papers contained in the report is one by Mr. N. H. Winchell on "The Crystalline Rocks, some preliminary considerations as to their Structure and Origin," and Dr. A. C. Lawson gives the results of a survey of the raised beaches of the north shore of Lake Superior.

A USEFUL syllabus of an elementary course of botany has been received from the author, J. Bentley Philip. It is published by James G. Bisset, of Aberdeen.

PROF. HERDMAN writes to us:—"During the Whitsuntide vacation the Liverpool Marine Biology Committee spent two days in dredging from Port Erin, and the rest of the time in work on the shore and in the Biological station. On one day the weather was sufficiently fine to allow of the steamer working on the seventy fathom depression which lies to the west of the Isle of Man, half way to the Irish coast. The bottom there is a fine stiff grey-blue mud or clay, which, it has been suggested, may be of glacial origin. We searched very carefully through dredgefuls of this unpleasantly tenaceous cold mud in the hope of finding some stones or shells which might settle the matter, but in vain. The animals on this ground include the Crustaceans *Calocaris macandreweæ* and *Pasiphæa sivado*, a Polynoid (*Panthalis oerstedi*) in enormous muddy tubes and *Lipobranchius jeffreysii*, Echinoderms *Amphiura chiajii* and *Brissopsis lyrifera* (in quantity), *Virgularia mirabilis*, and the Molluscs *Isocardia cor* and *Rissoa abyssicola*. On a previous trip, shortly before this, one of our party obtained fifteen living specimens of *Isocardia cor* on this ground. The rest of the dredging on the two days was carried on nearer Port Erin, along the west side of the Isle of Man, at depths of twelve to forty-six fathoms. Among the more noteworthy forms obtained were the Echinoderms *Thyone raphanus* and *Echinocardium flavescens*, a calcareous sponge *Ute glabra* (found before at Guernsey), the Ascidians *Eugyra glutinans*, *Polycarpa comata*, and a considerable number of the rare *Forbesella tessellata* (which present such variations in shape, general appearance, colour and texture, along with identity in anatomical characters, as to enable me to say that Forbes's *Cynthia tessellata* and *C. limacina* are undoubtedly one and the same species), and the mollusca *Oscanius membranaceus*, *Coryphella landsburgi*, and *Cyclostrema millepunctatum*, Friele, which is new to British seas. One of our reporters on Mollusca (Dr. Chaster) tells me that Canon Norman, who has seen our specimens of the *Cyclostrema*, and compared them with one of Herr Friele's type specimens in his collection, writes that the species has only been taken by the Norwegian North-Atlantic Expedition at Stat. 192 (Lat. 69°46′ N., Long. 16° 15′ E.), off the northern part of Norway, at a depth of 649 fathoms. *Anomalocera pattersonii* was very conspicuous in the surface nettings, and additional specimens of the new *Lichomolgus* (L.

maximus, Thomps.) inhabiting *Pecten* were obtained, along with many other Copepoda which have not yet been examined."

Two further papers upon his researches with the electric furnace are contributed by M. Moissan to the current number of the *Comptes Rendus*. In the first it is shown that crystals of quartz and zircon are almost instantly fused at the high temperature of a powerful electric arc, the liquids brought to vigorous ebullition in a few moments and actually distilled, passing over into the receiver in the form of a dense fume. M. Moissan further demonstrates how easy it is at this high temperature to obtain pure zirconium and pure silicon by reduction of the liquefied oxides with carbon. The current employed was one of 360 ampères. When fragments of rock crystal were placed in the crucible of the furnace and subjected to the arc they rapidly melted, and in seven minutes the liquid boiled vigorously; the vapour of silicon dioxide which escaped condensed in the cooler portion of the furnace to a bluish-white fume, which deposited in the receiver in the form of small opalescent spheres, visible to the unaided eye. These spheres of silica were solid throughout, and usually exhibited a depression at some portion of the surface, indicating contraction upon passing from the liquid to the solid state. They were readily soluble in hydrofluoric acid. It is of interest that M. Moissan has discovered similar opalescent spheres of silica upon glass globes which have been employed in electric lighting to diffuse the light from arc lamps, indicating that slow volatilisation of the silica of the glass had occurred. It is doubtless to this cause that the opalescence which usually occurs after such globes have been in use for some time is due. The specific gravity of the spheres is 2·4, slightly less than that of quartz. At the temperature of the arc given by 360 ampères liquid silica is very readily reduced by carbon, a crystalline regulus of silicon being obtained containing more or less carbon.

WHEN zircons or any other form of zirconia are submitted to the high temperature of the same arc they likewise fuse, and in about ten minutes the liquid boils vigorously, and zirconium oxide passes over as a white fume into the receiver, where it condenses in the form of a white powder. Any liquid remaining in the crucible after switching off the current solidifies to a crystalline mass, and scattered about the walls of the furnace numerous perfect little artificial zircons are observed, identical n colour, lustre, and other properties with natural zircons. Both these and the powder condensed in the receiver readily scratch glass. Liquid zirconia, like silica, is readily reduced by carbon. If the oxide is fused by the arc in a carbon crucible, a button of metallic zirconium is found at the close of the operation beneath the residual solidified zirconia. If zirconia is mixed with powdered carbon a metal is obtained containing 4-5 per cent. of carbon. This carbide can be refined by re-melting with more zirconia when the pure metal is obtained. Zirconium is a very hard metal, readily scratching glass and ruby. Its density is 4·25.

THE second paper of M. Moissan describes the preparation of metallic tungsten, molybdenum, and vanadium. Tungsten is readily obtained in the form of powder by reduction of heated tungstic acid in a current of hydrogen, but the powder thus obtained has been hitherto found to be practically infusible. M. Moissan now shows that tungsten may be readily prepared in solid ingots in the electric furnace. A mixture of tungstic acid and carbon is placed in the crucible, and after ten minutes' subjection to an arc of the tension above stated a button of over a hundred grams of the metal is produced. If care has been taken to ensure excess of tungstic acid, pure tungsten is btained in the one operation. Otherwise a carbide is obtained which requires refining by re-melting with a further quantity of tungstic acid. The tungsten thus obtained is a very brilliant metal of specific gravity 18·7. M. Moissan has further observed that if a much more powerful arc is employed, the percentage of carbon in the carbide of tungsten first obtained is very largely increased. Thus when a current of 1000 ampères was employed the percentage of carbon rose to 18, indicating an attempt to form a true binary compound. Metallic molybdenum has likewise been obtained by M. Moissan by the reduction of its oxide with powdered charcoal at the temperature of the arc afforded by a current of 360 ampères. The metal is not, however, quite free from carbon, and requires refining.

THE preparation of metallic vanadium has presented considerable difficulty. It will be remembered that Sir Henry Roscoe found it impracticable to reduce vanadic acid by carbon, and eventually isolated the pure metal by reduction of the dichloride in a stream of hydrogen. M. Moissan finds that even after twenty minutes' action of the arc from the 360 ampères current, only a trace of reduction is apparent at the surface of the mixture of oxide and charcoal. Upon increasing the tension of the arc by employing a current of a thousand ampères complete reduction occurs, but the metal produced combines, as in the case of tungsten, with a large quantity of carbon. It would appear, therefore, that at this high temperature these refractory metals combine with carbon to form definite binary compounds.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include the Actinians *Sagartia miniata* and *venusta*, the Nemertines *Amphiporus hastatus* and *Malacobdella grossa*, the Polychæte *Myrianida maculata* (with a posteriorly proliferated chain of buds), and the Schizopods *Siriella frontalis* and *jaltensis*, the latter species in considerable numbers. Floating Cœlenterates have been particularly plentiful. Medusæ of *Aurelia aurita* (now 4 to 7 ins. in diameter) have frequently been noticed. The Anthomedusæ have been represented by *Sarsia tubulosa*, *Bougainvillea ramosa*, and, more plentifully, by *Amphinema Titania*; the Leptomedusæ by countless numbers of *Phialidium variabile*, together with a smaller proportion of *Thaumantias Thompsoni* (Forbes) and *Laodice cruciata*, Ag. (= *T. pilosella*, Forbes). A few young *Clytia* medusæ have been occasionally taken, but *Obelia* medusæ have been very scarce. The Ctenophore *Hormiphora plumosa*, in various stages of growth, is now abundant. Several specimens of the parasitic larva of the Actinian *Halcampa chrysanthellum* have been taken. The beautiful veliger *Echinospira diaphana* has once been noticed; larvæ of the Crustacean *Porcellana* are plentiful. The following animals are now breeding:—The Hydroid *Clava cornea*, the Mollusca *Murex erinaceus* and *Aplysia punctata*, the Schizopoda *Macromysis inermis* and *Siriella jaltensis*, the Decapod *Palæmonetes vulgaris*, and the Echinoderm *Asterina gibbosa*.

THE additions to the Zoological Society's Gardens during the past week include a Barbary Ape (*Macacus inuus*, ♀) from North Africa, presented by Mr. A. G. F. Dashwood; a Suricate (*Suricata tetradactyla*) from South Africa, presented by Mr. L. V. Harcourt; three Chinese Quails (*Coturnix chinensis*, ♂ ♀ ♀) from China, presented by Mr. W. J. Ingram; two Kingfishers (*Alcedo ispida*) British, presented by Mr. A. K. Dixon; a Harlequin Snake (*Elaps fulvius*) from Florida, presented by Mr. C. Ernest Brewerton; a Horned Lizard (*Phrynosoma cornutum*) from Texas, presented by Mr. J. Harland Coates; a Sykes's Monkey (*Cercopithecus albigularis*, ♀) from East Africa, a Leucoryx (*Oryx leucoryx*, ♀) from North Africa, a Mexican Deer (*Cariacus mexicanus*, ♂) from Mexico, a Malayan Tapir (*Tapirus indicus*, ♂) from Malacca, two Common Cassowaries (*Casuarius galeatus*, jr.) from Ceram, a Leopard Tortoise (*Testudo pardalis*), two Derbian Zonures (*Zonurus derbianus*) from South Africa, deposited; two Brazilian Cariamas (*Cariama cristata*) from Brazil, four Black-tailed Godwits

(*Limosa ægocephala*) four Flamingoes (*Phœnicopterus antiquorum*) European, purchased; a Barbary Wild Sheep (*Ovis tragelaphus*, ♂), an Angora Goat (*Capra hircus*, ♀ var.), a Japanese Deer (*Cervus sika*, ♀), a Great Kangaroo (*Macropus giganteus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE TOTAL SOLAR ECLIPSE (April, 1893).—M. N. Coculesco, in the current number of the *Comptes Rendus* (No. 22) gives a brief account of his observations made during the last total solar eclipse. The station he occupied was at Fundium. The instruments which he took with him consisted of a telescope of 0·16 m. aperture, with a wooden mounting, a fine comet seeker, a mean time chronometer, and a thermometer. An ordinary photographic camera fixed to the telescope was also employed, five fine negatives of the corona being obtained with it. The plates employed were the ordinary dry plates of gelatine-bromide of silver, and the developer that of ferrous-oxlate. The exposures were of 2, 4, 6, 7, and 5 seconds duration, but the second plate seems to have given the most details. The observation of contacts gave the following results:—

Observation.	Paris M. T. h.	m.	s.
1st contact	2	20	21
2nd ,, ...	3	42	51
3rd ,, ...	3	47	2
4th ,, ...	5	3	36

thus giving 4m. 11s. as the duration of totality. The thermometrical observations showed that on the day of the eclipse the temperature was + 28° C., at the commencement of totality 26°·6, middle of totality 24°·0, and at the end of the eclipse 26°·5. A fall of from 3½° to 4° was thus noticed from the commencement of the eclipse to the middle of totality.

METEOR OBSERVATIONS.—Mr. Denning, in the *Observatory* for June, has a note on the large meteor of April 15, 1893, and also notes on observations of fireballs. With reference to the latter he points out those observations are made by a number of casual observers, and are commonly found to be conflicting and incomplete, the accounts being based on "rough hurried impressions often vitiated by serious errors." In attempting to reduce such observations it is generally found impossible to accommodate the descriptions unless we assume that the several large meteors appeared simultaneously in different paths. These bodies, he says, deserve closer attention than is usually given to them, and accurate observations should be made with regard to their positions, directions, and durations of their flights among the stars. That meteoric astronomy would advance by rapid strides, and that many "moot points in the visible behaviour of meteor-streams would soon receive settlement" cannot for a moment be doubted.

The study of brilliant meteors is one that requires no instrument but simply a good star atlas, and we hope that many of our readers may take Mr. Denning's words to heart and try to elevate this important branch of astronomy so that it can no longer be said that "they come and go, and their transient glories serve no more important end than that of affording startling spectacles to those who are fortunate enough to witness them."

WASHBURN OBSERVATIONS.—In vol. vi. part 3 of the Publications of the Washburn Observatory are the results of the observations made by Mr. Sidney Dean Townley of telescopic variable stars of long period. The method employed was to select two stars for comparison, one slightly brighter and the other slightly fainter than the one to be measured, the difference between these two comparison stars in brightness being less than a magnitude. By this means a very accurate estimation can be made of the brightness of the star in tenths of the interval between those taken for comparison. In estimating the magnitudes of the comparison stars he has employed the limit of visibility of the finder and large telescope (apertures 8·9 cm. and 39·5 cm. respectively), commencing with the former, and going down the numerical scale. The method of recording the values obtained is similar to the notation used by Argelander and Herschel Thus of two comparison stars *a* and *b*, *a* 1 *b* shows that the star observed is very nearly as bright as *a*, while *a* 9 *b* shows that it is very nearly equal in brightness to *b*, the number 1 representing one-tenth of the difference of brightness between the two comparison stars. In the tables, the number of the stars, together with their R.A.'s and declinations, are taken from Chandler's "Catalogue of Variable Stars." About 36 variables are included in this work, the observations extending over the period 1889–1892.

FINLAY'S COMET (1886 VII.).—Comet Finlay is described as circular, 1′ in diameter, 11th magnitude, very diffuse, and with no tail. As it rises just before the morning twilight in this country, it is by no means in a good position for observation. The following ephemeris is taken from a continuation of M. Schulhof's computations, made by M. Coniel, the difference between the computed and observed places being approximately—1m. 43s. in R.A. and + 12′ N.P.D.

M.T. Paris.

GEOGRAPHICAL NOTES.

AT the last meeting of the Royal Geographical Society, Dr. Joseph A. Moloney, medical officer to Capt. Stairs' expedition to Katanga, read a paper descriptive of the journey. The expedition of over 300 men landed at Bagamoyo on June 27, 1891, and marched to Lake Tanganyika through the German territory, following the well-known caravan-track through Tabora. On the way proofs were not wanting that the slave-traders were kept well supplied with gunpowder, in spite of the strict regulations which are made much of in Europe. On October 9 they reached Lake Tanganyika near its southern end, and from conversations with the missionaries and natives obtained some interesting information as to the variations in the level of the water. It appears that the outlet of the lake by the Lukuga becomes periodically choked by sand and vegetation, thus forming a natural dam, which causes the level of the lake to rise. After a time the barrier is carried away and the river issues with great force, flowing strongly for a number of years. The extreme difference in level must be about 18 feet, and the rise and fall probably occupy about fifteen years. On October 31 the caravan started from the west side of the lake. The Kaomba country first passed through was found to abound in minerals, iron and copper being extensively worked by the natives who show much skill in the manufacture of weapons and implements. Bunkeia, the capital of Msiri's territory, was reached on December 14, the journey having been of extraordinary rapidity considering the route taken. Much of the country was swampy, and there were tracts of dense tropical forests reminding Captain Stairs of the Aruwimi basin. Near Bunkeia a famine was raging, and this, together with the tragedies consequent on the conquest of Msiri, brought the expedition into a very bad state. All the Europeans except Dr. Moloney suffered severely, and Captain Stairs never fully recovered. On February 4, 1892, the survivors of the expedition set out on the return journey, and travelling by Lake Nyasa and the Shire reached the Chinde mouth of the Zambesi on June 4.

JUDGE DALY, President of the American Geographical Society, devoted his anniversary address, which has just been published, to a critical study of the portraits of Columbus. He believes that several of those popularly held to be authentic are really original paintings from the life, but the Lotto portrait which has been multiplied indefinitely by the United States Government on commemoration coins and postage stamps he looks on as of very doubtful value.

MR. CARL LUMHOLTZ publishes a letter from North Mexico in the last number of the *Bulletin* of the American Geographical Society, in which he gives some account of his studies of the Tarahumare Indians, who are cave-dwellers although not apparently connected with the ancient cave and cliff-dwellers of the United States. Mr. Lumholtz was engaged in taking down the language, and in making anthropometric measurements of this little-known tribe.

THE French weekly geographical paper, *La Géographie*, has, after five years in the ordinary garb of a newspaper, assumed a new form, each number consisting of eight quarto pages in a coloured wrapper.

MR. H. YULE OLDHAM, Lecturer on Geography in Owens College, Manchester, has been appointed to the lectureship on Geography in the University of Cambridge, formerly held by Mr. J. Y. Buchanan, F.R.S. Mr. Oldham has mainly studied the historical aspects of geography, and in his appointment the University of Cambridge obviously intends to associate its geographical teaching with the Historical rather than the Natural Science Board of Studies. It is to be hoped that the lectureship will receive more attention from the members of the University than has been given to it hitherto, and that the loss to scientific geography caused by Mr. Buchanan's retirement will be more than made up by increased interest in the less specialised aspects of the science.

MR. H. M. CADELL gives a remarkably interesting map of the site of Edinburgh in prehistoric times in the June number of the *Scottish Geographical Magazine*. The most noteworthy feature is the submergence of the 25 feet raised beach on which the greater part of Leith is now built, and the existence of seven comparatively large lakes of which the shrunken remnants only remain, or which have been entirely drained and reclaimed within the historic period. A summary of the evidence for the existence of these lakes is given in the form of a short article. It is noteworthy that the changes in the surface of the land due to cultivation and building operations have in some cases almost entirely concealed the original features. In the early human period the shores of the Firth of Forth must have been occupied by a succession of swampy lakes dominated by the steep cliffs of the volcanic hills.

SEISMOLOGY IN JAPAN.[1]

THE editor insists in a Wordsworthian manner on calling this the seventeenth volume although it is really vol. i. of the journal: he numbers it as a continuation of publications hitherto issued as the Transactions of the Seismological Society of Japan. The Society was founded in 1880 and for many years its meetings were frequent and well attended. It ceased to live in so far as subscriptions and meetings are concerned in 1892, many of its members having left the country. It may now be said to exist as much as ever it did, but without subscriptions. The transactions are in sixteen volumes of scientific papers to which a general index is published in this first number of the journal, and there can be no doubt of the great value of these papers, or of the ability and industry in experiment and speculation of the men who wrote them. During the twelve years' work of the Society much was accomplished; some order was evolved out of chaos; seismographs have been invented giving absolute measurements of earth motions, and a complete change has been effected in earthquake observation; a chair of seismology has been established in the Imperial University and there is now a bureau controlling a central observatory and some 700 outside stations, together with many seismological laboratories. This is some of the work which the Society has done.

The first paper in this journal "On the Mitigation of Earthquake Effects, and Certain Experiments on Earth Physics" by the editor, reads very strangely to any one unacquainted with the work done by Prof. Milne in the last fifteen years. For example, on the construction of buildings in earthquake countries, his experiments have led to such results that he can speak with certainty on things which used to be merely matters of vague speculation, such as the security given by depth of foundation and the great differences in the earth motions at places within a few hundred yards of one another.

Probably no one can speak with greater authority on photographic matters than Prof. Burton, who contributes an article "On the Application of Photography to Seismology and Volcanic Phenomena." The other papers are:—An abstract of "The Seismometrical Observations for the year 1890," by the editor; "An Account of Experiments on the Overturning and Fracturing of Brick and other Columns by Horizontally Applied Motion," by the editor and Prof. Omori; "On Earth Pulsations in relation to certain Natural Phenomena and Physical Investigations," by the editor; an abstract on observations by Dr. E. Von Rebeur-Paschwitz with horizontal pendulums; a note on old Chinese earthquakes, by Prof. Omori, and a note by the editor on the destructive earthquake of 1891. All these papers seem to me to be valuable and interesting; they ought to be studied by every young philosopher whose mathematical and other weapons are ready, but who is yet without mental employment. The subject is one of world-wide interest, although it may seem to be only interesting to people like the Japanese who are jogged into attention every week of their lives.

The beautiful series of photographs published by Burton and Milne about a year ago are records that can never be branded as lies or exaggerations. Even Dr. Johnson, who to his dying day denied the fact that an earthquake had occurred at Lisbon, would have been convinced by records such as these. Without these photographs it would be difficult to believe in the actual compression in area of land over a large district or in vertical wave motion, travelling along a street as if the earth were water in a canal. The Japanese cannot neglect the study of the subject and other people ought not. Our time also may come, even in England, when in a five seconds interval, three fourths of all the houses in London may tumble into ruin and a quarter of a million sterling may be lost on every square mile of English ground. It is of no use to argue from the long histories of ancient cities. Earth shakes that had no evil effect on the more or less pyramidal architecture of Assyria and Egypt would lay the dwelling houses of London in long swathes upon the ground. One laughs at Alice's White Knight who was so well prepared for sharks, but we also laugh at Mrs. Aleslime whose specific in the real time of danger was "black stockings for sharks." Whatever our own safety may be we must remember that some of the most interesting parts of the world are vitally interested in this question, and the most artistic, most honest, most kindly, most generous and confiding clever people that the world has ever seen are demanding from us that we shall study this question to find out whatever means there may be for mitigating the effects of earthquakes, and more than all, taking away from them the dreadful everpresent feeling of danger, which seems in itself almost sufficient to arrest progress in civilisation.

We western people were till lately represented in Japan on this question by the Seismological Society. What one earnest worker and a few of his friends can do is being done, but in spite of earnestness and devotion, I am afraid that in one respect there must be a lessened result. The existence of the Society was of some weight in maintaining the interest of the Japanese Government on what must seem to non-scientific people a rather hopeless search for information. Even the small and exceedingly intermittent assistance of the British Association grant is of enormous moral value to Prof. Milne; and I think that if the council at Edinburgh had yielded to the representations of section A and granted the modest request of Prof. Milne for £25, they would have done more good than they can do with any equal sum in their present list. We have here a man who is untiring in experimental work, who has the power of keeping enthusiasm alive in other people to a remarkable degree, who is not a wealthy man and who yet spends some hundreds of pounds a year of his own, in making and using apparatus and in publishing a journal which has about seventeen subscribers. And all the work is good; it is thankless work as all work on the beginning of a science must be.

If every reader of NATURE who is interested in the matter and who can afford it, would only send to Prof. Milne a subscription (one pound a year) to this journal, his losses would be confined to his experimental work; the Japanese Government would more certainly continue to interest its officials in making observations, and the subscribers would glow in the consciousness of having done their duty. JOHN PERRY.

[1] *The Seismological Journal of Japan*, edited by John Milne, F.R.S. Vol. xvii. 1893.

ON LIGHT AND OTHER HIGH FREQUENCY PHENOMENA.[1]

BRILLIANTLY worded, comprehensive, and strikingly illustrated was a lecture delivered by Mr. Nikola Tesla, of which a report has just reached us. In his own words:—

[1] A lecture delivered before the Franklin Institute, at Philadelphia, Feb. 24, 1893, and before the National Electric Light Association, at St. Louis, Mo., March 1, 1893.

"In presenting these insignificant results I have not attempted to arrange and co-ordinate them as would be proper in a strictly scientific investigation in which every succeeding result should be a logical sequence of the preceding, so that it might be guessed in advance by the careful reader or attentive listener. I have preferred to concentrate my energies chiefly upon advancing novel facts or ideas which might serve as suggestions to others, and this may serve as an excuse for the lack of harmony. The explanations of the phenomena have been given in good faith, and in the spirit of a student prepared to find that they admit of a better interpretation. There can be no great harm in a student taking an erroneous view, but when great minds err, the world must dearly pay for their mistakes."

The following extracts will serve to show the character of the discourse:—

The Action of the Eye.

It can be taken as a fact, which the theory of the action of the eye implies, that for each external impression, that is, for each image produced upon the retina, the ends of the visual nerves concerned in the conveyance of the impression to the mind, must be under a peculiar stress or in a vibratory state. It now does not seem improbable that, when by the power of thought an image is evoked, a distinct reflex action, no matter how weak, is exerted upon certain ends of the visual nerves, and therefore upon the retina. Will it ever be within human power to analyse the condition of the retina when disturbed by thought or reflex action, by the help of some optical or other means of such sensitiveness, that a clear idea of its state might be gained at any time? If this were possible, then the problem of reading one's thoughts with precision, like the characters of an open book, might be much easier to solve than many problems belonging to the domain of positive physical science, in the solution of which many, if not the majority, of scientific men implicitly believe. Helmholtz has shown that the fundi of the eyes are themselves luminous, and he was able to *see*, in total darkness, the movement of his arm by the light of his own eyes. This is one of the most remarkable experiments recorded in the history of science, and probably only a few men could satisfactorily repeat it, for it is very likely that the luminosity of the eyes is associated with uncommon activity of the brain and great imaginative power. It is fluorescence of brain action, as it were.

Another fact having a bearing on this subject which has probably been noted by many, since it is stated in popular expressions, but which I cannot recollect to have found chronicled as a positive result of observation is, that at times, when a sudden idea or image presents itself to the intellect, there is a distinct and sometimes painful sensation of luminosity produced in the eye, observable even in broad daylight.

Two facts about the eye must forcibly impress the mind of the physicist, notwithstanding he may think or say that it is an imperfect optical instrument, forgetting that the very conception of that which is perfect or seems so to him, has been gained through this same instrument. Firstly, the eye is, as far as our positive knowledge goes, the only organ which is *directly* affected by that subtile medium, which, as science teaches us, must fill all space; secondly, it is the most sensitive of our organs, incomparably more sensitive to external impressions than any other.

This divine organ of sight, this indispensable instrument for thought and all intellectual enjoyment, which lays open to us the marvels of this universe, through which we have acquired what knowledge we possess, and which prompts us to, and controls, all our physical and mental activity. By what is it affected? By light! What is light?

It is beyond the scope of my lecture to dwell upon the subject of light in general, my object being merely to bring presently to your notice a certain class of light effects and a number of phenomena observed in pursuing the study of these effects. But to be consistent in my remarks it is necessary to state that according to that idea, now accepted by the majority of scientific men as a positive result of theoretical and experimental investigation, the various forms of manifestations of energy which were generally designated as "electric" or more precisely "electromagnetic" are energy manifestations of the same nature as those of radiant heat and light. Therefore the phenomena of light and heat, and others besides these, may be called electrical phenomena. Thus electrical science has become the mother science of all and its study has become all-important. The day when we shall know exactly what "electricity" is, will chronicle an event probably greater, more important than any other recorded in the history of the human race.

Transformation of Currents.

Mr. Tesla then went on to describe the apparatus employed, and the method of obtaining the high potentials and high frequency currents which are made use of in his experiments. In order to explain the transformation of currents he used the following analogy:—

Imagine a tank with a wide opening at the bottom, which is kept closed by spring pressure, but so that it snaps off *suddenly* when the liquid in the tank has reached a certain height. Let the fluid be supplied to the tank by means of a pipe feeding at a certain rate. When the critical height of the liquid is reached, the spring gives way and the bottom of the tank drops out. Instantly the liquid falls through the wide opening, and the spring, reasserting itself, closes the bottom again. The tank is now filled, and after a certain time interval the same process is repeated. It is clear that if the pipe feeds the fluid quicker than the bottom outlet is capable of letting it pass through, the bottom will remain off and the tank will still overflow. If the rates of supply are exactly equal, then the bottom lid will remain partially open, and no vibration of the same and of the liquid column will generally occur, though it might, if started by some means. But if the inlet pipe does not feed the fluid fast enough for the outlet, then there will be always vibration. Again, in such case, each time the bottom flaps up or down, the spring and the liquid column, if the pliability of the spring and the inertia of the moving parts are properly chosen, will perform independent vibrations. In this analogue the fluid may be likened to electricity or electrical energy, the tank to the condenser, the spring to the dielectric, and the pipe to the conductor through which electricity is supplied to the condenser. To make this analogy quite complete it is necessary to make the assumption, that the bottom, each time it gives way, is knocked violently against a non-elastic stop, this impact involving some loss of energy, and that, besides, some dissipation of energy results, due to frictional losses. In the preceding analogue the liquid is supposed to be under a steady pressure. If the pressure of the fluid be assumed to vary rhythmically, this may be taken as corresponding to the case of an alternating current. The process is then not quite as simple to consider, but the action is the same in principle.

Electrostatic Force.

After showing that the human body could be traversed by a powerful electric current vibrating at about the rate of one million times per second, Mr. Tesla said:—

The amount of energy which may thus be passed into the body of a person depends on the frequency and potential of the currents, and by making both of these very great, a vast amount of energy may be passed into the body without causing any discomfort except perhaps in the arm, which is traversed by a true conduction current. The reason why no pain in the body is felt, and no injurious effect noted, is that everywhere, if a current be imagined to flow through the body, the direction of its flow would be at right angles to the surface; hence the body of the experimenter offers an enormous section to the current, and the density is very small, with the exception of the arm perhaps, where the density may be considerable. But if only a small fraction of that energy would be applied in such a way that a current would traverse the body in the same manner as a low frequency current, a shock would be received which might be fatal. A direct or low-frequency alternating current is fatal I think, principally because its distribution through the body is not uniform, as it must divide itself in minute streamlets of great density, whereby some organs are vitally injured. That such a process occurs I have not the least doubt, though no evidence might apparently exist or be found upon examination. The surest to injure and destroy life is a continuous current, but the most painful is an alternating current of very low frequency. The expression of these views, which are the result of long-continued experiment and observation, both with steady and varying currents, is elicited by the interest which is at present taken in this subject and by the manifestly erroneous ideas which are daily propounded in journals on this subject.

The electrostatic attractions and repulsions between bodies of measurable dimensions are, of all the manifestations of this force, the first so-called *electrical* phenomena noted. But though they have been known to us for many centuries, the precise nature of the mechanism concerned in these actions is still unknown to us, and has not been even quite satisfactorily explained. What kind of mechanism must that be? We cannot help wondering when we observe two magnets attracting and repelling each other with a force of hundreds of pounds with apparently nothing between them. We have in our commercial dynamos magnets capable of sustaining in mid-air tons of weight. But what are even these forces acting between magnets when compared with the tremendous attractions and repulsions produced by electrostatic force, to which there is apparently no limit as to intensity. In lightning discharges bodies are often charged to so high a potential that they are thrown away with inconceivable force and torn asunder or shattered into fragments. Still even such effects cannot compare with the attractions and repulsions which exist between charged molecules or atoms, and which are sufficient to project them with speeds of many kilometres a second so that under their violent impact bodies are rendered highly incandescent and are volatilized. It is of special interest for the thinker who inquires into the nature of these forces to note, that whereas the actions between individual molecules or atoms occur seemingly under any condition, the attractions and repulsions of bodies of measurable dimensions imply a medium possessing insulating properties. So, if air, either by being rarefied or heated, is rendered more or less conducting, these actions between two electrified bodies practically cease, while the actions between the individual atoms continue to manifest themselves.

Single-wire Transmission.

It has been for a long time customary, owing to the limited experience with vibratory currents, to consider an electric current as something circulating in a closed conducting path. It was astonishing at first to realise that a current may flow through the conducting path even if the latter be interrupted, and it was still more surprising to learn, that sometimes it may be even easier to make a current flow under such conditions than through a closed path. But that old idea is gradually disappearing, even among practical men, and will soon be entirely forgotten.

It is thought useful to devote here a few remarks to the subject of operating devices of all kinds by means of only one leading wire. It is quite obvious, that when high-frequency currents are made use of, ground connections are—at least, when the E.M.F. of the currents is great—better than a return wire. Such ground connections are objectionable with steady or low frequency currents on account of destructive chemical actions of the former and disturbing influences exerted by both on the neighbouring circuits; but with high frequencies these actions practically do not exist. Still, even ground connections become superfluous when the E.M.F. is very high, for soon a condition is reached when the current may be passed more economically through open, than through closed conductors. Remote as might seem an industrial application of such single wire transmission of energy to one not experienced in such lines of experiment, it will not seem so to any one who for some time has carried on investigations of such nature. Indeed I cannot see why such a plan should not be practicable. Nor should it be thought that for carrying at such a plan currents of very high frequency are implicitly required, for just as soon as potentials of say 30,000 volts are used, the single wire transmission may be effected with low frequencies, and experiments have been made by me from which these inferences are made.

Electrical Resonance.

Some remarks and experiments were then made with regard to electrical resonance. Continuing, Mr. Tesla said:—

In connection with resonance effects and the problem of transmission of energy over a single conductor which was previously considered, I would say a few words on a subject which constantly fills my thoughts and which concerns the welfare of all. I mean the transmission of intelligible signals or perhaps even power to any distance without the use of wires. I am becoming daily more convinced of the practicability of the scheme, and though I know full well that the great majority of scientific men will not believe that such results can be practically and immediately realised, yet I think that all consider the developments in recent years by a number of workers to have been such as to encourage thought and experiment in this direction. My conviction has grown so strong that I no longer look upon this plan of energy or intelligence transmission as a mere theoretical possibility, but as a serious problem in electrical engineering, which must be carried out some day. The idea of transmitting intelligence without wires is the natural outcome of the most recent results of electrical investigations. Some enthusiasts have expressed their belief that telephony to any distance by induction through the air is possible. I cannot stretch my imagination so far, but I do firmly believe that it is practicable to disturb by means of powerful machines the electrostatic condition of the earth, and thus transmit intelligible signals and perhaps power. In fact, what is there against the carrying out of such a scheme? We now know that electric vibration may be transmitted through a single conductor. Why then not try to avail ourselves of the earth for this purpose? We need not be frightened by the idea of distance. To the weary wanderer counting the mile-posts the earth may appear very large, but to that happiest of all men, the astronomer, who gazes at the heavens and by their standard judges the magnitude of our globe, it appears very small. And so, I think, it must seem to the electrician, for when he considers the speed with which an electric disturbance is propagated through the earth all his ideas of distance must completely vanish.

A point of great importance would be first to know what is the capacity of the earth? and what charge does it contain if electrified? Though we have no positive evidence of a charged body existing in space without other oppositely electrified bodies being near, there is a fair probability that the earth is such a body, for by whatever process it was separated from other bodies—and this is the accepted view of its origin—it must have retained a charge, as occurs in all processes of mechanical separation. If it be a charged body insulated in space its capacity should be extremely small, less than one-thousandth of a farad. But the upper strata of the air are conducting, and so, perhaps, is the medium in free space beyond the atmosphere, and these may contain an opposite charge. Then the capacity might be incomparably greater. In any case it is of the greatest importance to get an idea of what quantity of electricity the earth contains. It is difficult to say whether we shall ever acquire this necessary knowledge, but there is hope that we may, and that is by means of electrical resonance. If ever we can ascertain at what period the earth's charge, when disturbed, oscillates with respect to an oppositely electrified system or known circuit, we shall know a fact possibly of the greatest importance to the welfare of the human race. I propose to seek for the period by means of an electrical oscillator, or a source of alternating electric currents. One of the terminals of the source would be connected to earth, as, for instance, to the city water mains, the other to an insulated body of large surface. It is possible that the outer conducting air strata or free space contains an opposite charge and that, together with the earth, they form a condenser of very large capacity. In such case the period of vibration may be very low and an alternating dynamo machine might serve for the purpose of the experiment. I would then transform the current to a potential as high as it would be found possible and connect the ends of the high tension secondary to the ground and to the insulated body. By varying the frequency of the currents and carefully observing the potential of the insulated body and watching for the disturbance at various neighbouring points of the earth's surface resonance might be detected. Should, as the majority of scientific men in all probability believe, the period be extremely small, then a dynamo machine would not do and a proper electrical oscillator would have to be produced and perhaps it might not be possible to obtain such rapid vibrations. But whether this be possible or not, and whether the earth contains a charge or not, and whatever may be its period of vibration, it certainly is possible—for of this we have daily evidence—to produce some electrical disturbance sufficiently powerful to be perceptible by suitable instruments at any point of the earth's surface.

Production of Light.

The light effects which it has been the chief object to investigate can be divided into four classes: (1) Incandescence of a solid. (2) Phosphorescence. (3) Incandescence or phosphorescence of a rarefied gas, and (4) Luminosity produced in a gas at ordinary pressure. The first question is, How are these luminous effects produced? In order to answer this question as satisfactorily as I am able to do in the light of accepted views and with the experience acquired, and to add some interest to this demonstration, I shall dwell here upon a feature which I consider of great importance, inasmuch as it promises, besides, to throw a better light upon the nature of most of the phenomena produced by high frequency electric currents. I have on other occasions pointed out the great importance of the presence of the rarefied gas, or atomic medium in general, around the conductor through which alternate currents of high frequency are passed, as regards the heating of the conductor by the currents. My experiments described some time ago have shown that the higher the frequency and potential difference of the currents, the more important becomes the rarefied gas in which the conductor is immersed, as a factor of the heating. The potential difference, however, is, as I then pointed out, a more important element than the frequency. When both of these are sufficiently high, the heating may be almost entirely due to the presence of the rarefied gas. [Experiments were performed showing the importance of the rarefied gas, or generally of gas at ordinary or other pressure as regards the incandescence or other luminous effects produced by currents of this kind.]

Incandescent Lamps.

Disregarding now the modifying effect of convection, there are two distinct causes which determine the incandescence of a wire or filament with varying currents, that is, conduction current and bombardment. With steady currents we have to deal only with the former of these two causes, and the heating effect is a minimum, since the resistance is least to steady flow. When the current is a varying one the resistance is greater, and hence the heating effect is increased. Thus if the rate of change of the current is very great, the resistance may increase to such an extent that the filament is brought to incandescence with inappreciable currents, and we are able to take a short and thick block of carbon or other material and bring it to bright incandescence with a current incomparably smaller than that required to bring to the same degree of incandescence an ordinary thin lamp filament with a steady or low frequency current. This result is important, and illustrates how rapidly our views on these subjects are changing, and how quickly our field of knowledge is extending. In the art of incandescent lighting, to view this result in one aspect only, it has been commonly considered as an essential requirement for practical success, that the lamp filament should should be thin and of high resistance. But now we know that the resistance to the steady flow of the filament does not mean anything; the filament might as well be short and thick; for if it be immersed in rarefied gas it will become incandescent by the passage of a small current. It all depends on the frequency and potential of the currents. We may conclude from this, that it would be of advantage, so far as the lamp is considered, to employ high frequencies for lighting, as they allow the use of short and thick filaments and smaller currents.

If a wire or filament be immersed in a homogeneous medium, all the heating is due to true conduction current, but if it be enclosed in an exhausted vessel the conditions are entirely different. Here the gas begins to act and the heating effect of the conduction current, as is shown in many experiments, may be very small compared with that of the bombardment. This is especially the case if the circuit is not closed and the potentials of course very high. Suppose a fine filament enclosed in an exhausted vessel be connected with one of its ends to the terminal of a high tension coil and with its other end to a large insulated plate. Though the circuit is not closed, the filament, as I have before shown, is brought to incandescence. If the frequency and potential be comparatively low, the filament is heated by the current passing *through* it. If the frequency and potential, and principally the latter, be increased, the insulated plate need be but very small, or may be done away with entirely; still the filament will become incandescent, practically all the heating being then due to the bombardment. . . . It should not be thought that only rarefied gas is an important factor in the heating of a conductor by varying currents, but gas at ordinary pressure may become important, if the potential difference and frequency of the currents is excessive. On this subject I have already stated, that when a conductor is fused by a stroke of lightning, the current through it may be exceedingly small, not even sufficient to heat the conductor perceptibly, were the latter immersed in a homogeneous medium.

From the preceding it is clear that when a conductor of high resistance is connected to the terminals of a source of high frequency currents of high potential, there may occur considerable dissipation of energy, principally on the ends of the conductor, in consequence of the action of the gas surrounding the conductor. Owing to this, the current through a section of the conductor at a point midway between its ends may be much smaller than through a section near the ends. Furthermore, the current passes principally through the outer portions of the conductor, but this effect is to be distinguished from the skin effect as ordinarily interpreted, for the latter would or should occur also in a continuous incompressible medium. If a great many incandescent lamps are connected in series to a source of such currents, the lamps at the ends may burn brightly, whereas those in the middle may remain entirely dark. This is due principally to bombardment, as before stated. But even if the currents be steady, provided the difference of potential is very great, the lamps at the ends may burn more brightly than those in the middle. In such case there is no rhythmical bombardment, and the result is produced entirely by leakage. This leakage or dissipation into space, when the tension is high, is considerable when incandescent lamps are used, and still more considerable with arcs, for the latter act like flames. Generally, of course, the dissipation is much smaller with steady than with varying currents.

Incandescence of Gases.

Coming now to the incandescence or phosphorescence of gases at low pressures or at the ordinary pressure of the atmosphere, we must seek the explanation of these phenomena in shocks or impacts of the atoms. Just as molecules or atoms beating upon a solid body excite phosphorescence in the same or render it incandescent, so when colliding among themselves they produce similar phenomena. But this is a very insufficient explanation, and concerns only the crude mechanism. Light is produced by vibrations which go on at a rate almost inconceivable. If we compute, from the energy contained in the form of known radiations in a definite space the force which is necessary to set up such rapid vibrations, we find, that though the density of the ether be incomparably smaller than that of any body we know, even hydrogen, the force is something surpassing comprehension. What is this force, which in mechanical measure, may amount to thousands of tons per square inch? It is electrostatic force in the light of modern views. It is impossible to conceive how a bod of measurable dimensions could be charged to so high a potential that the force would be sufficient to produce these vibrations. Long before any such charge could be imparted to the body it would be shattered into atoms. The sun emits light and heat, and so does an ordinary flame or incandescent filament, but in neither of these can the force be accounted for if it be assumed that it is associated with the body as a whole. Only in one way may we account for it, namely, by identifying it with the atom. An atom is so small, that if it be charged by coming in contact with an electrified body and the charge be assumed to follow the same law as in the case of bodies of measurable dimensions, it must retain a quantity of electricity which is fully capable of accounting for these forces and tremendous rates of vibration. But the atom behaves singularly in this respect, it always takes the same "charge."

It is very likely that resonant vibration plays a most important part in all manifestations of energy in nature. Throughout space all matter is vibrating, and all rates of vibration are represented, from the lowest musical note to the highest pitch of the chemical rays, hence an atom, or complex of atoms, no matter what its period, must find vibration with which it is in resonance. When we consider the enormous rapidity of the light vibrations, we realise the impossibility of producing such vibrations directly with any apparatus of measurable dimensions and we are driven to the only possible means of attaining the object of setting up waves of light by electrical means and economically, that is, to affect the molecules or atoms of a gas, to cause them to collide and vibrate.

Much would remain to be said about the luminous effects produced in gases at low or ordinary pressures. With the present experiences before us we cannot say that the essential nature of these charming phenomena is sufficiently known. But investigations in this direction are being pushed with exceptional ardour. Every line of scientific pursuit has its fascinations, but electrical investigation appears to possess a peculiar attraction, for there is no experiment or observation of any kind in the domain of this wonderful science which would not forcibly appeal to us. Some beautiful experiments with a vacuum tube concluded the lecture.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Observatory Syndicate have prepared a report with respect to the future work of the Cambridge Observatory.

They are of opinion that in the present condition of Astronomy provision must be made for photographic work, so that their inquiries have been directed to the discovery of the best scheme for rendering the Northumberland Equatorial available in connection with the project for a photographic establishment. The primary question as to the respective merits of reflectors and refractors for the photographic instrument had of course to be considered. On this issue there is considerable difference of opinion. For producing representations of astronomical objects, where great detail is required, reflectors are the most suitable. But where accurate measurement of the photographic plates is the object in view the balance of opinion seems clearly to show that the refractor is better adapted than the reflector. As it seems obvious that the work undertaken at the Cambridge Observatory should be based on accurate measurement the Syndicate have come to the conclusion that the refractor is the photographic telescope that should be employed. They think it right, however, to draw the attention of the University to the kindness of Mr. Common who offered to make and present to the Observatory a suitable silvered glass mirror if it were decided to employ the reflecting instrument.

It may be well to add that the Newall Telescope is devoted in the main to spectroscopic work and further that this instrument having been made for visual observation is not adapted to the special photographic work to which it is now proposed to direct the energies of the Observatory.

The scheme which the Syndicate suggest is that a new objective of eighteen inches aperture corrected for the photographic rays be provided; that the focal length of this should be about the same as that of the Northumberland objective, for which a new tube will be required; and that the two objectives, united as a pair like the present instruments at Greenwich and Oxford, should be erected on a new mounting, under a new dome, in the building at present occupied by the Northumberland Equatorial.

It will be observed that, by this scheme, the Northumberland objective will still be useful for every purpose for which it has been hitherto employed, with the great additional advantages of an excellent mounting and a good clock work. For example, such observations of comets as have been previously made here can be conducted under circumstances of much greater convenience than before. As to the special work to be undertaken by photography, it appears to the Syndicate that for the present under the particular conditions in which work here can be conducted there is no subject so promising as stellar parallax. The Director of the Observatory desires to undertake a systematic search with the aid of photography for stars which have measurable parallax, and of course so complete an apparatus as is now proposed would be available for many other researches besides that just suggested.

A preliminary estimate for the new telescope and mounting complete makes the cost £2450. To this must be added £500 for the new dome, and £150 for the measuring apparatus. If £100 be added for extras this makes a total of £3200. There is now a sum of about £1500 in the Special Sheepshanks Fund available for the purchase of instruments. In view of future contingencies, to exhaust the Sheepshanks Fund would be unadvisable and indeed it would not suffice for the purchase of an 18-inch equatorial. As such an instrument would contribute largely to the astronomical services of the Observatory the Syndicate think that an appeal to the public for subscriptions would probably be successful and such an appeal they are prepared to make.

It is therefore recommended that they be authorised to obtain estimates and plans for a new instrument as above described.

Dr. Hill, Master of Downing College, has been appointed a representative of the University at the International Medical Congress to be held at Rome next September.

SCIENTIFIC SERIALS.

American Meteorological Journal, May.—The following are the principal meteorological articles:—Meteorology as the physics of the atmosphere, by Prof. W. v. Bezold. This is a translation by Prof. C. Abbe of the first part of an important paper from *Himmel und Erde*. It describes the problems which at present are the subject of theoretical investigation, and points out what new problems have grown from looking at observational meteorology from a theoretical point of view. During the last decade attention has been chiefly devoted to the development of the so-called convection theory, which is principally based on observations at the earth's surface, but which, at higher elevations, is found to have defects. It has therefore become necessary to try and connect this theory with that of the old trade-wind theory, which for several decades has been entirely set aside. More attention is required to observations made in the higher regions of the atmosphere, together with the application to them of the principles of general mechanics, as well as of thermo-dynamics.—Charts of storm frequency, by Prof. Abbe. The author has plotted in a tabular form the number of storm centres that pass over each quadrangular degree between lat. 20° and 49° N., and long. 99° and 63° W., deduced from the tri-daily Signal Service charts, from March, 1871, to February, 1873. He states that the chart from which the table is prepared clearly shows that the storm tracks, which move from Alberta and Assinniboin south-eastward over the United States and then north-eastward towards the gulf of St. Lawrence, describe a system of parabolic curves whose tendency is to have a common point of intersection, and therefore a region of maximum storm frequency, in, or to the north-west of Nebraska.—Six and seven day weather periodicities, by H. H. Clayton. The author, who has studied the subjects of periodicities for several years, found a striking regularity between the intervals of many of the temperature maxima of the Blue Hill observations, and that almost all the maxima could be arranged in such a way that they followed each other at intervals of six or seven days. He thinks that, for a large part of the year, forecasts of temperature, on the assumption of regular rhythmic oscillations, and a knowledge of the time of their beginning and ending, may be made for a week or two in advance with nearly as much accuracy as they are now made by the Weather Bureau for thirty-six hours.

American Journal of Mathematics, vol. xv., No. 2. (Baltimore, April, 1893).—The opening memoir is one entitled "Hyperelliptische Schnittsysteme und Zusammenordnung der Algebraischen und Transcendentalen Thetacharacteristiken," by H. D. Thompson (pp. 91–123). There are numerous figures and an index of contents.—On the determination of groups whose order is a power of a prime, by J. W. A. Young (pp. 124–178), considers in some detail groups of the order specified in extension of the work on groups by Cayley (*Am. J. of Math.*, vol. i.), Kempe (*Phil. Trans.*, vol. clxxvii.), Netto (Substitutionentheorie, pp. 133–7), and Kronecker. The author's aim has been "to presuppose no knowledge of the theory of groups on the part of the reader."—The third paper, the projection of fourfold figures upon a three-flat, by T. P. Hall (pp. 179–189), is an interesting contribution to the literature of higher space, and the last page (190) contains a note on a geometrical theorem by C. N. Little. It gives a property of a Pascal line, and a Brianchon point of 6 gons formed in a specified manner.

Wiedemann's Annalen der Physik und Chemie, No. 5.—On electrical discharges: production of electrical oscillations and their relation to discharge tubes, by H. Ebert and E. Wiedemann. This portion of the work investigates the manner in which the properties of the conducting circuit determine the sensibility of the discharge-tube when placed in a given position with regard to the terminal condenser. Among the conditions thus studied were the distance between the plates of the primary condenser, the D.P. in the primary spark-gap, and the frequency of the sparks; also the influence of bridges across the wire system, the D.P. required to make the tubes glow, and the effects of the presence of other glowing tubes in the field. As regards the last, it was found that if a glowing gas was present in a portion of the condenser field the distribution of energy was quite different from that in a homogeneous field; the tubes of energy were attracted towards the gas and passed through it, showing that the gas in the state of glow has a greater permeability for the electric flux.—On the diffraction of light at the straight sharp edge of a screen, by Eugen Maey. This work was undertaken to test whether a certain diffraction phenomenon was explainable by the accepted theory of diffraction. The phenomenon in question, as described by W. Wien, consists in the fact that a finely-ground metallic edge, when illuminated by an intense white light, appears as a bright line from points deep in the geometrical shadow. A careful theoretical and experimental study of the phenomenon shows that the theory is competent to explain the fact within certain limits, but that the phenomenon is greatly influenced by small differences of excellence in the edges, a circumstance which has an important bearing upon the behaviour of gratings.—Absolute measurements on the discharge of electricity from points, by Julius Precht. In general, points may be charged highly before discharge begins. Lightning conductors require about 15,000 volts, and the finest points 2500. Ultra-violet illumination favours discharge, whereas dust and flame gases diminish it. A bundle of equal points requires a higher potential than a single one. A point discharging positive electricity wears away, whilst a point negatively electrified does not.—Also papers by O. Wiener, J. von Geitler, M. Levy, A. Kossel, and A. Raps.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 4.—"Further Experimental Note on the Correlation of Action of Antagonistic Muscles." By C. S. Sherrington, M.A., M.D.

In a previous communication (Proceedings of Royal Society, February 1, 1893) it was stated that physiological contraction, and even mere mechanical tension, of the *flexor muscles* of the knee exerts considerable physiological influence upon the activity of the antagonistic group of muscles, the *extensors.* For instance, the elicitation of the "jerk" from the extensors can be rendered difficult for a time by appropriate excitation of the flexors, and can on the other hand be much facilitated by flaccidity or paralysis of the latter.

In order to judge whether under these circumstances the briskness of the "knee-jerk" varies directly with the degree of tonus of the extensor muscles, the rapidity of onset of rigor mortis, has been chosen as a guide to the degree of tonus existing in them before death. The experiments of Brown-Séquard and Hermann have proved that section of the nerve supplying a muscle delays the time of onset of rigor mortis in the muscle, even if the section is performed only shortly before death. There was therefore examined the influence of section of the motor spinal roots on the time of onset of rigor mortis, and a delay of onset of rigor mortis was thus produced. The delay seemed as considerable as after section of the entire muscular nerve. The effect of section of the sensory roots was next examined, and found to be marked retardation of onset of rigor; the retardation was less if the spinal cord were previously severed in the region of the first lumbar segment. The effect of placing and keeping one hind limb in the pose most favourable for the elicitation of the "jerk" (knee flexed) and the other limb in the position in which the jerk is restrained (knee extended) was then investigated (always after previous severance of the spinal cord at the first lumbar segment). On the side on which the knee had been kept flexed the onset of rigor mortis was delayed in the extensor muscles, whereas on the opposite side, with the knee extended rigor was delayed in the flexors. It was inferred that the tonus of extensors is heightened by excitation of the antagonistic set, and conversely.

In regard to the mutual association of action of antagonistic muscles about other joints than the knee, it had been noticed in an earlier series of observations that during excitation of the cortical areas of the hemisphere, when isolated movements of the pollex and hallux are being initiated, the movement of response obtained is often reversed by section of the peripheral nerve or nerves supplying those muscles which predominate in the movement obtained. For example, flexion can by section of the flexor nerve be at once converted into extension. Sometimes, however, movement in the same sense, although diminished in force and extent persists even after cutting the nerve to the predominant group of the antagonistic muscles. This indicates that in some cases there occurs, together with contraction of one group of muscles, concomitant relaxation of the antagonist. This evidence of inhibition of one set of the synergetic muscular couple during co-ordinate action induced by cortical excitation is in the case of the digits of comparatively infrequent occurrence. In the case of the eye muscles it is, on the contrary, quite usual.

When, the external rectus muscle of one eye (*e.g.*, of the left eye) having been put out of action, the frontal cortex of the right hemisphere is excited, the eyeballs if previously directed to the right revert both of them to the left—*i.e.*, the excitation which evokes contraction of the right internal rectus evokes also relaxation of the left internal rectus. Again, when the internal rectus has been put out of action—*e.g.*, in the left eye—excitation of the left frontal cortex produces, if the eyes have been previously directed to the left, an immediate movement of both eyeballs to the right, the left eye frequently rotating beyond the median primary position. Here the same excitation of the cortex which induces contraction of right external rectus muscles induces synchronously a relaxation of the left internal rectus muscle. These interruptions of the tonus or of the contraction of one antagonist concurrently with augmentation of the contraction of its opponent are obtainable not only from the so-called "motor" region of the cortex, but even more strikingly by excitation of the "visual area" of occipital region of the cortex.

During voluntary movements similar phenomena occur, but appear less obvious than under experimental excitation of the cortex. Although inhibition of contraction or tonus is apparently so common a factor in the co-ordination of the antagonistic lateral straight muscles of the eyes, these muscles occasionally yield good indication of synergetic contraction as well as co-ordinate relaxation. The mutual association of the two oblique muscles seems usually of the nature of concomitant contraction, not of contraction coupled with relaxation. On the other hand, the muscles which close and open the palpebral fissure appear to work altogether independently one of the other. In their case section of the particular peripheral nerve concerned in either movement is at once followed by total disappearance of the movement, and that without reversal.

Although the cerebral cortex exercises inhibition so readily in the field of innervation of the third nerve, the dilatation of the pupil evoked by excitation of that portion of the cortex appeared whenever tested to be due to impulses discharged *viâ* the cervical sympathetic, and not to inhibition of the constriction exercised *viâ* the third nerve.

May 18.—"An Experimental Investigation of the Nerve Roots which enter into the Formation of the Lumbo-Sacral Plexus of *Macacus rhesus.*" By J. S. Risien Russell, M.B., M.R.C.P., Assistant Physician to the Metropolitan Hospital.

(From the Pathological Laboratory of University College, London.)

This formed the subject of a paper recently read before the Royal Society, in which the author described one chief type of plexus met with in *Macacus rhesus*, the main distinguishing features of which, as contrasted with the chief variation encountered, consisted in the fifth lumbar nerve root sending a branch to the sciatic nerve trunk, and the obturator nerve taking its origin from the fourth and fifth lumbar nerve roots alone, whereas of the variations met with that which occurred most frequently was one in which the fifth lumbar root did not send a branch to the sciatic nerve, and the obturator nerve received a branch from the sixth lumbar nerve root in addition to those received from the fourth and fifth lumbar roots. Between these two extremes all forms of variation were met with; but the upper limit of supply to the limb was always found to be the third lumbar root, and the lower limit the first sacral root.

Excitation Experiments.

The movement which results on excitation of any given nerve root with the Faradic current is a compound one made up of several simple movements; while excitation of any single small bundle of nerve fibres, many of which combine to form a nerve root, results in a single simple movement, and not all the movements of the compound root in lessened degree. These single simple movements bear an almost constant relation to the nerve roots, the same movements being as a rule found in any given root, and such movements always bear the same relation to the spinal level. Further, each bundle of nerve fibres representing a single simple movement in a nerve root remains distinct in its course to the muscle or muscles, producing such a movement without inosculating with other motor nerve fibres.

Muscles diametrically opposed in their action are represented in the same nerve root, but in different degrees, and when a certain group of muscles predominate in their action in one root they as a rule predominate in that root. In those instances in which the opposed movements are represented in three consecutive nerve roots the middle root of the series is that in which both movements are represented, while the root above contains the one movement, and that below contains the other.

The movements of flexion and extension are found to alternate in their representation from above down, flexion being at a higher level than extension in the highest segment of the limb, while extension is above flexion in the next, and so on.

A muscle is usually represented in two nerve roots, and to an unequal extent in these; and when variations occur, it is, as a rule, that one of the nerve roots in which the muscle is represented is different, rather than that it is represented in more nerve roots. When the same muscle is represented in two nerve roots the muscle fibres innervated by one root are not innervated by the other, so that only part of the muscle contracts when a single root is excited.

Ablation Experiments.

Division of any given nerve root produces paresis of the group of muscles supplied by it, which paresis is temporary, nearly all of it being recovered from. The amount of paresis or paralysis produced is proportional to the number of nerve roots divided; and this again varies according to whether the roots divided are consecutive or alternate ones, the effect being much greater in the former than in the latter case. Such division of one or more nerve roots does not result in incoordination of the remaining muscular combinations represented in other nerve roots; the remaining movements are merely more feeble.

Exclusion of a certain Root or Roots during an Epileptic Convulsion in the Limb.

Division of one or more nerve roots produces alteration of the position of a limb during an epileptic convulsion, which altered position depends on the muscular combinations that have been thus thrown out of action. And the effect is identical when the root or roots are divided at the time when the convulsions are evoked, and when they have been divided some weeks previously. No incoordination is produced in the remaining muscular combinations; and there is no evidence of overflow of the impulses which ought to travel down the divided root into other channels through the spinal centres, so as to reach the muscles by new paths.

"A Further Minute Analysis by Electric Stimulation of the so-called Motor Region (Facial Area) of the Cortex Cerebri in the Monkey (*Macacus sinicus*)." By Charles E. Beevor, M.D., F.R.C.P., and Victor Horsley, M.B., F.R.C.S., F.R.S. [1]

(From the Laboratory of the Brown Institution, and from the Pathological Department of University College, London.)

In the paper of which this is an abstract the authors have completed the minute analysis of the movements elicited by excitation of the excitable (so-called motor) region of the cortex cerebri in the Bonnet Monkey (*Macacus sinicus*). The portions hitherto examined having been those in which the movements of the limbs were represented, the facial area was chosen for the present research. After an historical introduction and a description of the anatomy of the region investigated, the method of notation and record of results is discussed.

Considering that in this part of the cortex cerebri there is well-defined representation of movements of both sides of the body, the question of bilaterality of representation is raised, and attention directed to its importance. The analysis of the results obtained show that there existed precise localisation for the movements of the individual portions of the face, even to that of half the lower lip.

The specialisation of the movements of the tongue was rendered easy of examination by employing the operative device of dividing the tongue in the middle line. This shed unexpected light on the representation of the movements of this organ.

Movements of the pharynx were made the subject of observation, and some degree of unilaterality was discovered in the movements of the soft palate.

Finally, attention is drawn to the fact that the marches of movements in succession are in this region very inconstant and difficult to arrange.

[1] The expenses of this research were defrayed principally by a grant from the Government Grant Fund of the Royal Society, and in part by a grant from the Scientific Grants Committee of the British Medical Association.

"On the presence of Urea in the Blood of Birds, and its bearing upon the Formation of Uric Acid in the Animal Body." By Sir Alfred Garrod, M.D., F.R.S.

The author gives in his paper a *résumé* of the opinions held with regard to the formation of uric acid in the animal economy during the last half century, and then announces his discovery of the presence of urea in the blood of birds in quantities practically the same as that which is present in the mammalian blood; by which discovery the views hitherto held as to the formation of uric acid are necessarily modified. Having afterwards shown that the kidneys have no power of removing uric acid from blood, and referred to other physiological points in connection with uric acid and urea, he sums up most of his views in the following propositions:—

First. That in mammalia and other urea-excreting animals the metabolism of the nitrogenised tissues results in the formation of urea as an ultimate product; that an appreciable and measurable amount of this substance is always found in their blood, and is constantly being excreted by the kidneys; and, further, that any cause leading to the decrease of this excretion produces an augmentation of the urea in the blood.

Second. That in birds, and other uric-acid-excreting animals, the metabolism of the nitrogenised tissues is exactly the same as in mammals, and that urea is the ultimate product of this metabolism; that urea is always present in their blood, in quantities not less than in mammalian blood, and that the urate of ammonium is a subsequent product of the union of urea with some other principle or principles, glycine probably being one of them. Consequently, it is not necessary that uric acid should be present in the blood of uric-acid-excreting animals: in health, in fact, it is not detectible. When it is present, its presence is a result of its having been absorbed after formation in the kidneys or elsewhere.

Geological Society, May 24.—W. H. Hudleston, F.R.S., President, in the chair.—The following communications were read:—Notes on Dartmoor, by Lieut.-General C. A. McMahon. The author alluded to a memoir on the British Culm Measures recently published by Mr. Ussher, in which the view is advanced that the granite of Dartmoor resulted from the metamorphism of pre-existing rocks which had in a rigid state offered obstruction to a long sustained N. and S. squeeze, and that their fusion and consequent consolidation were effected *in situ*. The author gave some of the results of a visit to the western borders of Dartmoor. He detailed some examples of eruptive granite-veins intruding into Culm beds in the immediate vicinity of the main mass of granite. The latter, in the locality described, is porphyritic down to its boundary, and the veins are also porphyritic. All the circumstances lead to the belief that these veins are real apophyses from the main mass, and that the view adopted by De la Beche regarding the origin of the Dartmoor granite is the true one. After alluding to some features in the Meldon granite-dyke not before noted, some detailed observations in the bed of the River Tavey were given, and an explanation offered of the way in which the fine-grained marginal variety of the granite, seen in that locality, has been produced. The improbability that a tremendous squeeze sufficient to fuse 225 square miles of a pre-Devonian rock into granite while the Culm Measures outside the zone of marginal contact-metamorphism are left almost untouched was commented upon, and finally, the author alluded to the often-observed pseudo-stratification of the Dartmoor granite, and urged that the cause of this is not the one suggested by De la Beche, but that it is due to sub-aerial agencies. The reading of the paper was followed by a discussion in which the President, Mr. Watts, Mr. Teall, Mr. Rutley, Prof. Bonney, and Prof. Hull took part. General McMahon briefly replied.—On some recent borings through the lower Cretaceous strata in East Lincolnshire, by A. J. Jukes-Browne. The borings described in this paper are at Alford, Willoughby and Skegness, and disclose the existence of an unsuspected anticlinal axis, bringing up Lower Cretaceous rocks beneath the

Drift. In the Willoughby boring, beneath the Drift, a brown sand was obtained, apparently the "Roach" division of the Lower Cretaceous, and below it the Tealby Clays (108 feet), oolitic ferruginous beds (18 feet), and sandstone and sand regarded as the Spilsby Sandstone. In the Alford boring the highest solid rock appears to belong to the basal beds of the Red Chalk, and below it is Carstone, and then clay. The axis of the anticlinal appears to pass between Alford and the border of the wolds, and is probably continued in a north-westerly direction beyond the village of Claythorpe. The result of the information now obtained makes it probable that the Chalk tract which lies to the south-east of the Calceby valley is completely isolated from the rest of the Chalk area. The President said that the lesson of the paper was that it was never safe to take anything for granted when one had to deal with Boulder Clay, and Mr. Strahan remarked that he agreed with Mr. Jukes-Browne's interpretation of the structure of the district.

Linnean Society, May 24.—Anniversary meeting.—Prof. Stewart, President, in the chair.—The treasurer presented the accounts duly audited, and the secretary having announced the elections and deaths during the past twelve months, the usual ballot took place for new members of Council, when the following were elected:—Messrs. J. G. Baker, A.C.L. Günther, G. R. Murray, R. C. A. Prior, and Howard Saunders. The President and officers were re-elected. The librarian's report having been read and certain formal business disposed of, the President delivered his annual address, taking for his subject "The various modes in which animal sounds are produced." On the motion of Dr. Braithwaite, seconded by Sir James Gibson Maitland, Bart., a unanimous vote of thanks was accorded to the President for his address, with a request that he would allow it to be printed. The Society's gold medal was then formally presented to Prof. Daniel Oliver, in recognition of the services rendered by him to botanical science, and having been acknowledged by Prof. Oliver, the proceedings terminated.

CAMBRIDGE.

Philosophical Society, May 15.—Prof. T. McK. Hughes, president, in the chair.—The following communications were made to the Society:—Exhibition of abnormal forms of *Spirifera lineata* (Martin) from the Carboniferous Limestone, by F. R. Cowper Reed. This species, as defined by Davidson, is normally subject to great variation of form and ornamentation, as it includes *Sp. imbricata* and *Sp. elliptica*. Specimens with intermediate characters are however common. The series of abnormal forms exhibited showed the gradual development of a sharp median groove both in the dorsal and ventral valves so as ultimately to produce a bilobed shell. From the nature of these grooves interruption of the shell-secreting action of the mantle seems to have occurred along a definite line: and the cause may have been disease, the presence of a parasite or foreign body, or pressure during life. Similar malformation is seen in some Terebratulas, &c. The normal and regular bilobation of some species of *Orthis*, *Terebratula*, &c., is comparable.—Exhibition of Post-Glacial Mammalian bones from Barrington recently acquired by the Museum of Zoology, by Mr. S. F. Harmer.—Exhibition of a specimen showing Karyokinetic division of the nuclei in a plasmodium of one of the *Mycetozoa*, by Mr. J. J. Lister.—Observations on the Flora of the Pollard Willows near Cambridge, by Mr. J. C. Willis and I. H. Burkill.—The plants occurring in the tops of willows near Cambridge have been recorded during the last few years, and amount to 80 species, occurring 3951 times altogether in about 4500 trees. Of these 80, only 18 form more than 1 per cent. of the total number of records. The rest have only a small number of records. As Loew has pointed out in a recent paper, these plants are of interest from the points of view of distribution of seeds and of epiphytism. Classifying them according to means of distribution, we find that 19 species have fleshy fruits; 1763 records (44.6 per cent.) of these occur. Three species with burrs have 651 records (16.4 per cent.); 34 species with winged or feathered fruit or seed have 996 records (25.1 per cent.); 7 with very light seeds have 421 (10.6 per cent.); and finally of plants whose means of distribution is poor or somewhat doubtful, we have 17 species with 120 records (2.9 per cent.). It is thus shown very strikingly how the various distribution mechanisms succeed, only the better ones showing in the list any numbers. The bird-distributed plants figure much higher here than in such cases as *e.g.* the flora of the churches of Poitiers (Richard), because birds visit the trees to such an extent. The observations show clearly the fact that a seed is only carried a short distance by its distribution mechanism. Plants were always found upon the soil, within 250 yards at most, of those found in the trees. An analysis was taken as far as possible of the birds' nests found in the trees, and pieces, often with ripe fruits, of many plants in the list were discovered in them, so that probably this means of distribution is of some importance. With regard to epiphytism, Loew considers these plants as exhibiting a commencement of this mode of life, and this seems probable enough. Like the regular epiphytes, they possess good methods of seed distribution. Their position does not call for any special means of supporting themselves, and the supply of humus is plentiful. *Mycorhiza*, which Loew found on many, was not observed in the few examined. The size of many of the shrubs, *e.g.* Elder, *Ribes*, Roses, &c., was very remarkable; some elders were three inches thick or more, and as much as 12 feet high. Experiments are in progress upon the growth of plants in willow humus.—Note on the plants distributed by the Cambridge dust-carts, by I. H. Burkill.—The street-sweepings of Cambridge have of late been spread on Coe Fen for the purpose of raising the level. From this material spring the plants whose seeds have been scattered in the dust of the roads. Of these, 99 species and one variety have been collected. No less than 39 per cent. are species whose dissemination has been effected directly or indirectly by Man, being either used for food or maintained in the gardens. The other species are almost all such as seed freely on roadsides, and have for the most part very light seeds.

DUBLIN.

Royal Dublin Society, May 17.—Prof. G. F. Fitzgerald, F.R.S., in the chair.—Dr. G. Johnstone Stoney, F.R.S., read a paper on the cause of sun-spots. In this communication the author recalled attention to the explanation of sun-spots which he had offered in 1867, in a paper on the physical constitution of the sun and stars, published in the Proceedings of the Royal Society, No. 105, 1868. He pointed out that the discoveries since made through the spectroscope, and the details of the photosphere revealed to us in the photographs taken by Prof. Janssen at Meudon, have brought to light striking confirmations of this explanation. The photosphere, according to the author's view, consists of incandescent sooty clouds, and the cloudy regions constitute the bright patches seen in Prof. Janssen's photographs, each of which is in general some hundreds of miles broad and several hundreds of miles long. Inasmuch as the greater part of the radiation emanates from them, they must form a stratum of minimum temperature. In the interstices between the patches and in those larger openings which are known as sun-spots, a less luminous background is brought into view. This is either a second layer of cloud which is of transparent material like terrestrial clouds, or it is a position in which both the density suddenly becomes greater and at which there is a sudden transition from transparent atmosphere above to opacity beneath. This would present the appearance of the reflecting surface of a molten ocean. Now, by the "Law of Exchanges," such an ocean as is supposed by the second hypothesis, being capable of reflecting incident light abundantly, or such a cloud of transparent material as is supposed by the first hypothesis, being capable of scattering incident light abundantly, would either of them radiate much less abundantly than the sooty clouds which constitute the photosphere, and would therefore appear black in comparison, whether at the same temperature, or at higher temperatures up to a certain limit. One or other of these, then, appears to be that dark background seen in sun-spots and in the intervals between the patches of photosphere. The appearance of penumbra seen in most sun-spots and in many of the intervals between the patches of photosphere would be presented wherever the sooty clouds are thin, and not sending down the abundant showers which seem elsewhere to prevail, and which in faculæ are continuous over immense spaces.—Mr. Thomas Preston attracted the attention of the Society to a simple, direct, and perfectly general method of expressing the efficiency of a reversible engine in terms of the temperatures of the source and refrigerator. He also mentioned that the cycle originally described by Carnot requires no correction, and depends on no theory of heat. Carnot begins with an adiabatic transformation, and his cycle consequently possesses all the advantages of the "corrected" cycle proposed by Maxwell.

The commonly accepted version of Carnot's method is therefore an injustice to the celebrated author of "The Motive Power of Heat."

PARIS.

Academy of Sciences, May 29.—M. de Lacaze-Duthiers in the chair.—Studies on diffraction gratings; focal anomalies, by M. A. Cornu. Gratings, although trustworthy enough to be used for determining wave-lengths of light, yet present various anomalies which might cast some doubt upon the rigour of the optical principles upon which their construction is based. In order to study these perturbations in detail and to eliminate the attendant errors, M. Cornu constructed a machine for the automatic ruling of lines spaced according to fixed laws, so as to produce and exaggerate at will the anomalies whose origin was to be verified. Thus the systematic error in the position of the focus of spectrum images was reduced to two distinct and purely geometrical causes: In plane gratings, to the existence of a feeble curvature of the ruled surface; in a plain or curved grating, to the existence of a regular variation in the distance apart of the lines. In most cases these two causes co-exist, which makes the laws of the optical phenomenon highly complex.—On the volatilisation of silica and zirconia, and the reduction of these compounds by carbon, by M. Henri Moissan (see Notes).—Preparation in the electric furnace of some refractory metals: tungsten, molybdenum, vanadium, by M. Henri Moissan (see Notes).—On the preparation of zirconium and thorium, by M. L. Troost. An intimate mixture of zirconia and finely comminuted sugar charcoal, the former being in excess, is strongly compressed into small discs and placed in a carbon retort. It is then subjected to the action of the voltaic arc supplied by a current of 35 ampères and 70 volts, the retort being placed in a closed chamber traversed by a slow current of carbonic acid, so as to prevent the air from burning and retransforming the metal into zirconia. The reduction is immediate, and gives rise to small metallic masses which are not pure zirconium, but a true carburet of zirconium, corresponding to the formula ZrC_2. If the carbon retort is lined with zirconia the ingot is gradually freed from carbon, and leaves the pure metal behind. This has a steel-grey colour and is extremely hard. It scratches glass deeply, and is untouched by the best files. In air it is unaltered at ordinary temperatures. At a red heat it oxidises at the surface if containing little carbon, but burns brightly if containing much. It is not attacked by acids except by hydrofluoric acid, which acts even if greatly diluted. Thorium is prepared in an exactly similar way from the chloride. The reduction takes place more readily, giving rise to a carburet, ThC_2. The metal is very brittle, and less hard than zirconium. It decomposes water in the cold, evolving hydrogen and a hydrocarbon of pungent odour. In contact with air it gradually swells up and forms a powder which burns with greater rapidity and brightness than zirconium.—Observations on the volatilisation of silica, *à propos* of M. Moissan's communication.—On the phenacite of Saint-Christophe en Oisans, by MM. A. Des Cloizeaux and A. Lacroix.—On ordinary differential equations which possess fundamental systems of integrals, by M. Sophus Lie.—The total solar eclipse observed at Fundium (Senegal) on April 16, 1893, by M. N. Coculesco.—On geometrical properties which only depend upon spherical representation, by M. C. Guichard.—On surfaces with lines of curvature plane in both systems and isothermals, by M. Th. Caronnet.—Theorems relating to analytical functions of n dimensions, by M. G. Scheffers.—On a general property of fields admitting of a potential, by M. Vaschy.—On the densities of some gases and the composition of water, by M. A. Leduc.—On the rigidity of liquids, by M. J. Colin.—Action of acetic anhydride upon linalol; transformation into geraniol, by M. G. Bouchardat.—A general method for the analysis of butters, by M. Raoul Brullé.—On the physiology of the crayfish, by M. L. Cuénot.—Mechanism of the hyperplasic process in epithelial tumours; applications, by M. Fabre-Domergue.—Researches on the modifications of the excretion of urea in the course of certain surgical maladies, and especially after great operations; consequences from the point of view of therapeutics and treatment after operations, by M. Just Championnière.

BERLIN.

Physical Society, May 12.—Presidents, at first Prof. Kundt, and later Prof. du Bois Reymond.—Dr. E. Pringsheim gave an account of his further researches on the cause of the emission of light by heated gases. By the method already employed for sodium (see NATURE, vol. xlv., p. 312) he had recently tested the vapours of lithium, thallium, and potassium. At the highest temperature, at which nickel was fused, the vapours of these metals similarly gave an emission-spectrum following on the absorption spectrum as long as reduction processes were excluded. They at once showed their characteristic spectral lines as soon as the salt used, or the silicate formed from the metal in contact with the surface of the porcelain tube, was reduced either by hydrogen, by the metal itself, or by iron. The experiment of Dewar and Liveing, in which, by heating lithium with potassium and sodium in an atmosphere of hydrogen in an iron tube, they obtained the lithium-line, was explained by the speaker as due to the above-named cause, viz., a compound is formed of iron and lithium, which is then reduced and exhibits both emission and absorption. Dr. Pringsheim concluded from his experiments in support of his views that the four elements—lithium, sodium, thallium, and potassium—are not luminous when simply heated above the temperature of the flame in which they ordinarily exhibit their characteristic spectra. He believed rather that they only show emission and absorption spectra when they are in the nascent state resulting from processes of chemical reduction.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—A Treatise on Elementary Dynamics, 2nd edition: S. L. Loney (Cambridge University Press).—An Introduction to Practical Bacteriology: Dr. W. Migula, translated by M. Campbell (Sonnenschein).—Some Hints on Learning to Draw: G. W. C. Hutchinson (Macmillan).—The Hawks and Owls of the United States in their Relation to Agriculture (Washington).—The Geological and Natural History Survey of Minnesota, 20th Annual Report (Minn.).—Missouri Botanical Garden, Fourth Annual Report (St. Louis, Mo.).—Modern Microscopy: M. I. Cross and M. J. Cole (Baillière).—Geological and Solar Climates: M. Manson (Dulau).—British Forest Trees: J. Nisbet (Macmillan).—Darwin and Hegel: D. G. Ritchie (Sonnenschein).—Lectures on Sanitary Law: A. W. Blyth (Macmillan).—Fragments of Earth Lore: Prof. J. Geikie (Edinburgh, Bartholomew).—The Lepidoptera of the British Islands, vol. 1, Rhopalocera: C. J. Barrett (L. Reeve).—Hypnotism, Mesmerism, and the New Witchcraft: E. Hart (Smith, Elder).

PAMPHLETS.—Die Klimate der Geologischen Vergangenheit: E. Dubois (Nijmegen, Thieme).—Notes on the Gasteropoda of the Trenton Limestone of Manitoba, with a Description of One New Species: J. F. Whiteaves.—Sulla Dissipazione di Energia in un Campo Elletrico Rotante e Sulla Isteresi Elettrostatica: R. Arnò (Roma).

SERIALS.—Brain, Parts 61 and 62 (Macmillan).—Engineering Magazine, June (New York).

THURSDAY, JUNE 15, 1893.

APPLIED CHEMISTRY.

Dictionary of Applied Chemistry. By Prof. T. E. Thorpe, F.R.S., assisted by eminent contributors. Vol. iii., completing the work. (London: Longmans, 1893.)

THE completion of Dr. Thorpe's Dictionary, upon which both men of science and of practice may with truth congratulate him and his contributors, opens out the question how far such a work, however well done, can or cannot supply the needs at once of the layman, of the scientific man, and of the manufacturer. Perhaps this standard may be too high a one to apply to any single work, and yet I think that in many respects these three volumes will be found satisfactorily to fulfil the above requirements. That in some instances this cannot be said to be the case is not only not to be wondered at but almost to be expected, when we remember the extent of the ground covered, the complexity of the questions considered, and, above all, the difficulty which persons not actually engaged in the various industries experience in obtaining the latest details of new and improved methods and processes. In looking through this volume one is struck with the care which the editor has taken to carry out the condition that the articles on special manufactures ought to be written by scientific men who are themselves engaged in conducting the industry, rather than by those who can only look on those questions from outside. To give examples of this is easy. Take the article on Borax (Sodium Borate) written by Mr. E. L. Fleming. The reader will at once see, by comparing this with any descriptions of the process of preparing borax given in the text-books, that this article is full of data which have hitherto been either ignored or incorrectly given. Again "Sugar," written by Messrs. Newlands, extending over twenty-two pages, is a typical case of descriptions of processes written by persons well acquainted with the details of the operations and able to describe them clearly, and, what is important, care has been taken to illustrate the article by excellent figures of plant. Closely connected with this subject, and also admirably treated by Mr. Heron, a practical authority, to whom we likewise owe an exhaustive article on saccharimetry not to be equalled in any work of the kind, is a description of starch manufacture, in which the newest processes are described and the construction of the most recent apparatus well shown. Then the articles, "Pottery" and "Porcelain," written by Mr. Burton, of Wedgwoods, is another example of processes described by one who knows what he is writing about. Another remarkable instance of the same thing is that of the article, "Phosphorus," by Dr. J. B. Readman. Hitherto the detail of phosphorus manufacture has been a *mare clausum* to the scientific world—and so well have the secrets of the trade been kept, that in no treatise, whether purely scientific or otherwise, have the particulars of the production of phosphorus been hitherto made known. Now for the first time we have, from the pen of one who was himself engaged in the industry, a complete description not only of the methods adopted for making both white and red phosphorus, but likewise the manufacturing details as to yield, which are invaluable. It seems that the explanation given in the books as to the preparation of this important element has been altogether wrong. It has been generally supposed that only so much sulphuric acid is added to the bone-phosphate as will form the acid phosphate, $CaH_4(PO_4)_2$, and that this yields metaphosphate, $Ca(PO_3)_2$, when heated to redness, so that when this latter is distilled with charcoal only two-thirds of the phosphorus are reduced, and one-third remains behind as tricalcium phosphate. This view turns out to be wholly incorrect. In practice enough sulphuric acid is added to convert all the lime present into sulphate, so that it is metaphosphoric acid, (HPO_3), and not calcium metaphosphate, which on distillation with charcoal gives phosphorus, and the yield amounts to about 68 per cent. of the theoretical.

In a notice like the present it is not possible to do more than to run through a few of the most interesting articles in alphabetical order. I take first that on Oils, by Mr. A. H. Allen, of Sheffield, an authority on this somewhat difficult subject. No less than thirty-eight pages are devoted to the description of fixed oils and fats, especially with respect to their classification and identification by analysis, in which the newest and most improved methods are given. I fail, however, to find the name of Chevreul mentioned, to whom chemistry owes the first and still classical research on fats. Then I next take "Oxalic Acid and the Oxalates," a short article by the editor, whose valuable contributions, be it here said, form no inconsiderable fraction of the total 1058 pages. He has not stated the interesting fact quoted in the report published by Drs. Schunck, Smith, and myself in 1862, which, although ancient history, is still true, that from two pounds of sawdust no less than one pound of crystallised oxalic acid is obtained by Dale's process. Nor do I find any mention of manganese oxalate, which is now a marketable product, and is used as a drying agent for oils, and has the advantage over the other "driers," inasmuch as they colour the oil, whereas manganese oxalate can be used so as to yield an almost colourless drying oil. Omissions such as these are, as I have said, not to be wondered at, and I quote them with the object of pointing out that this Dictionary, admirable as it is, cannot replace such sources of information on applied chemistry as the journal of the Society of Chemical Industry, but that it must rather be considered as an introduction to such a mine of wealth as this journal—which I may call a child of my own—contains, and to add, as I feel bound to do, that some of the writers would have done well to refer more fully to its twelve volumes before completing their articles.

Next comes "Oxygen," written by Dr. L. T. Thorne, of Brin's Oxygen Company, and here I may notice a misprint on p. 83—and say that such misprints are singularly rare throughout the book, reflecting great credit on both editor and printer—which has puzzled me. In the description of Robbin's process a reference is given P.J. [2] 5. 436. I looked in vain through the *Journal für Praktische Chemie*, and only after some time discovered that P.J. should be Ph. (the *Pharmaceutical Journal*). A more important error remains to be noticed in this paragraph. How a mixture of 3 mols. of barium chloride and 1 mol of potassium bichromate, on treatment with

H

sulphuric acid *in the cold*, can yield oxygen I could not understand but, on looking up the original paper, I find that for barium chloride, barium peroxide should have been printed. Here CrO_3 and H_2O_2 mutually decompose to Cr_2O_3 and water, whilst pure oxygen derived from both sources comes off. This interesting reaction is not a new one, as it was used by Brodie in 1851, and adverted to in a lecture by Faraday at the Royal Institution; nor does it appear to be capable of producing oxygen at a sufficiently low cost to be of practical value. Of course, Dr. Thorne gives an excellent description of Brin's well-known process by which oxygen is now manufactured on a large scale, but I do not find any statement of a process which bids fair to compete with Brin, viz. Fanta's improvement on Tessie du Motay's reaction, by which oxygen is evolved from manganate of soda by the action of steam. He does indeed refer to Du Motay, and gives the cost of oxygen prepared by his process at from £3 to £4 per 1000 cubic feet, whereas that by the Brin process is given as from 3*s.* to 7*s.* I cannot help thinking that this proportional cost is incorrect, as I know that Fanta's process, the patent of which appears to have superseded Bowman's, is now in practical operation at the Bradford Gas Works, and this would scarcely be the case if the cost were as great as Dr. Thorne states.

That pure oxygen can now be produced at so low a figure as 3*s.* per 1000 cubic feet is a great fact, and induces the hope that we may ere long see it at 1*s.* per 1000. In that case the use of oxygen to heighten the temperature of combustion would become general, especially for welding and riveting of steel and iron. Even now its uses are spreading, not only for the oxyhydrogen light, but for purifying coal-gas. The addition of from 0·5 to 1·0 per cent. of oxygen to crude coal-gas renders its purification more complete and easy, as thus the sulphur compounds are reduced to 12 grains per 1000 cubic feet, and lime alone suffices as a purifying agent. Moreover, the luminosity of the gas is said to be increased. This application of oxygen is on its trial at certain gasworks, but it has to be shown how far this plan of adding oxygen acts more satisfactorily than the much cheaper one of the addition of air, in spite of the small loss in illuminating power which the presence of atmospheric nitrogen entails.

Next I turn to "Paper," by Mr. E. J. Bevan, a short but good article, in which I find a description, in which one misses some illustrations, of the method of recovering the soda used in the preparation of the esparto and other fibres used in making paper. No example of the applications of science to the working up of waste products is more striking than this. Before the introduction of the Rivers Pollution Act of 1876, no paper-maker thought of recovering his soda—all the liquors went to pollute the streams on which the works are situated. Now most paper-mills recover their soda, and save thereby from 80 to 85 per cent. of this costly article, whilst at the same time they have diminished the nuisance which they caused to their neighbours on the stream below them. It is high time that every user of soda for disintegrating or bleaching fibres of all kinds should be prohibited from thus fouling the water, and that the application of the "best practicable means" clause were rigidly enforced by all local authorities interested in improving the quality of the water of our rivers.

The article on "Petroleum," by Mr. Boverton Redwood, is another instance of information given by a high authority. It extends over forty pages, is up to date, and abundantly illustrated. "Photography," by Prof. J. M. Thomson, gives a clear and concise account of the chief processes of the application of photography to lithography and mechanical printing, now becoming more and more perfect, and the article concludes by giving a list of the more important works on the subject.

The two longest articles in the volume are, as might be guessed, Sodium and its compounds, occupying 93 pages and Sulphuric Acid and its relatives, taking up 84. The manufacture of sodium is one of the most remarkable advances of the time; not long ago it could only be bought by the ounce, and at an exorbitantly high price, now an order for 100 tons will be executed by the Aluminium Company, of Oldbury, and the price is only a few shillings a pound. Castner's process for making sodium is fully described, but the excellent illustrations are only of historic interest, inasmuch as the process which they indicate has lately been superseded by a more economic one. The article on Sodium Chloride is of a most complete and trustworthy character, and has been written by Mr. J. I. Watts, of Messrs. Brunner, Mond, and Co., where he has had ample opportunities of making himself master of every detail of the processes he describes. Sulphur and Sulphuric Acid are interesting articles by Dr. Alder-Wright, who adds to his scientific knowledge practical experience of the manufacture. I cannot pretend to discuss the merits—which are great—of these articles. I will only remark that they contain information up to date, and I am glad to see that Dr. Wright has consulted the *Journal of Chemical Industry*, and has given the readers of the Dictionary an opportunity of becoming acquainted with Dr. Hurter's researches on the chemistry of the leaden chamber, published in that journal.

The important article "Water" is contributed, as it should be, by Prof. Percy Frankland. With regard to this able article, extending over fifty-five pages, I have to remark that the author, whilst giving an excellent account of the chemistry of water, seems to have forgotten that he is writing an article in a dictionary of applied and not in one of pure chemistry. Why, for example, should two pages of valuable space be taken up by a long table of the tension of aqueous vapour? Nor is it clear that so many analyses of mineral waters need be quoted, no less than fifteen pages being taken up by tabular matter. On the other hand, greater prominence might well have been given to more technical details of the various methods of water purification. Here I think that the author might have given some extracts from the volumes of the Chemical Industry Society with profit, where, as he well knows, much new and important information is to be found. There is not a single diagram or illustration in this article showing the arrangements proposed for filtration or other means of purifying water; thus, whilst the author refers to the "Stanhope" purifier, he gives no drawing to explain its construction. Prof. Tilden's important experiments on the corrosive action of water on brass and copper are not referred to, a classical subject originally investigated by Davy in 1824, and reported upon by him to the Admiralty of that day. Nor is the paper of Mr. V. C. Driffield on the practical details on the use of carbonate of soda for softening water for boilers, important to every manufacturer, mentioned. Points such as these, which I might multiply, are needed by the practical man, and ought to have found a place in such a work.

Last, but not least, I will refer to the article on "Wine," written by Prof. Thorpe, which is of interest as giving a luminous account of vintage and vinification, and of the chemical changes which the vegetable acids present in the grape undergo during the process of wine-making. I miss, however, reference to the Pasteurisation of wine and to the classical researches of the great French chemist on the diseases of wine. Perhaps, however, the editor has rightly conceived that such matters, however important, do not quite come within the scope of "applied chemistry," and that the omission is intentional. I should have liked to refer to many other matters of interest with which this volume teems, but I have compassion on your space. Again I congratulate all concerned in the production of this Dictionary, which will, I feel sure, long continue as the standard work in our language.

H. E. Roscoe.

A POPULAR ATLAS.

The Universal Atlas. Containing 117 Pages of Maps and an Alphabetical Index of 125,000 Names. (London, Paris, and Melbourne. Published for the Atlas Publishing Company, Limited, by Cassell and Company, Limited, 1893.)

THIS Atlas, published in a strong cloth binding at 30*s.* net, is certainly unique in the British Market, and in its serial form it has already obtained a deservedly wide circulation.

There is no kind of publication of which the British public is so ignorant as a map, and the fact that few purchasers can tell the difference between a good map and a bad one has produced its natural effects. One of these is that the reviews of atlases in literary journals and the daily press are usually characterised by a tone of forced praise, and rarely go beyond free quotation from the publisher's preface or prospectus. It is more difficult to review a map than a book on account of the immense amount of concentrated information it contains, and even those who are competent for the task are often inclined to shrink from the close study and careful comparison which are necessary. The quality and price of the *Universal Atlas* are so unusual that we feel justified in examining it with some care, and in offering a few suggestions for its further improvement.

The work is published for an unknown company by Messrs. Cassell. There is no hint as to who designed the atlas or drew the maps or engraved the plates, or produced the book. The only indication borne by each sheet is "Printed in Leipzig." German map-printers are good, but there are atlases made in London and Edinburgh which are much better than this; unfortunately they are also much more expensive. One effect of the present publication will, we hope, be to call forth native work designed so as to hold its own in cost as well as quality with that of Germany. Meanwhile the *Universal Atlas* deserves success as a pioneer. We strongly object, however, to the practice—not unknown to some British mapmakers—of issuing the work of trained scientific men without acknowledgment; and of republishing earlier maps without mentioning the fact. If Messrs. Cassell had bound up with the Atlas the "history," which they print as a separate advertisement, and if the name of the printer to whom the creditable appearance of the work is due appeared upon it, we would have almost unqualified praise to bestow on them. As it is, however, we must plainly say that they have not done justice either to the memory of Andree, who prepared the original maps, or to the skill of Mr. W. J. Turner, who so admirably translated them, or even to the enterprise of Mr. H. O. Arnold-Forster, the chairman and presumably the promoter of the publishing company. We regret also that Messrs. Cassell did not entrust the printing to some firm in this country; although the first cost might have been greater, we do not believe that the profit would ultimately prove less.

Not knowing who the editor of the English edition of the Atlas is, we must blame the publishers for failing to adjust the balance of representation to English requirements. Germany is treated with undue detail; the United Kingdom is not adequately shown. Large parts of Germany are given on the scale of 1:870,000; no part of Great Britain is shown larger than 1:1,000,000. No enlargements of English industrial regions, or the environs of British towns appear, although Andree's German edition contains two on the scale 1:750,000. Many of the Continental sheets, on the other hand, are crowded with valuable insets giving details of special districts. The Colonies are, on the whole, very well shown; Canada has a fair amount of space, Africa is lavishly treated, and India is clearly mapped, although the scale is comparatively small. But Queensland, New Zealand and Tasmania, British Guiana, and all the small Asiatic colonies, have been slighted. It is interesting, however, to find Fiji, Samoa, and the West Indies given on a scale making each island show as a visible disc, which displays some little topographical detail. We would suggest that the neglected parts of the empire, some of the more important South American States (the delineation of which is far too small), and the central part of the United States, should have more space devoted to them. Room might be provided by suppressing the large scale map of Alsace-Lorraine, and the rather blurred map of Hungary on p. 51 (also Bohemia, p. 52), which have the scale of 1:2,500,000, and show scarcely more detail than does the general map of Austria-Hungary, pp. 47, 48, which is on the very similar scale of 1:2,750,000.

It is undesirable to enter into a minute criticism of individual maps, for the best workers cannot avoid occasional mistakes, and the most diligent revision has hard work to keep pace with the unceasing changes of railways, populations, and boundaries. We may notice, however, that Aberdeen, Bolton, Cardiff, Croydon, Preston, and Reims have now populations exceeding 100,000, and should be designated by the special sign set apart for towns of the first magnitude. Ross and Cromarty have ceased to exist as separate counties, and the care bestowed on colouring and lettering the detached fragments of these and other counties in Scotland is consequently thrown away. The railways and telegraphs of South Africa are far behind the age, the Orange Free State being shown as if still undisturbed by the engine's whistle. The cable (p. 5) to the Cape by the west coast is only partly shown, though correctly given in the German original; and the Bermudas are now in electrical touch with the world, though this does not appear on the map. There are surprisingly few errors of spelling, and for the general purposes of the newspaper reader the atlas is eminently serviceable.

Only a few physical maps are given, including two pages of familiar and rather feeble astronomical diagrams, the use of which must be very slight. The world in hemispheres is shown with an attempt at orographical colouring on the land, and there are bathymetrical charts of the Atlantic and Pacific Oceans. The latter are somewhat remarkable. The contour lines of depth are given as 110, 1100, 2200, 2750, and 3300 fathoms, those odd numbers corresponding of course to even depths in metres, but the occasional soundings dotted over the surface are stated not in fathoms, but in feet. Similarly the one small climate map shows isotherms drawn to represent centigrade degrees, but lettered with the approximate Fahrenheit equivalents. The system of showing the winds on this map is arbitrary, and the arrangement it implies is unnatural. The physical maps might indeed be excised without serious loss.

The plan of printing the hill-shading—usually much generalised—in brown, throws out the black lettering, admirably, while the rivers and railways are very clearly shown in most cases. The importance of clear maps in following any movement or distribution cannot be overestimated, and the Switzerland (pp. 53, 54), Caucasus (p. 71), and Greece (p. 72), in this atlas are beautiful examples of artistic work, embodying ample detail without confusion.

OUR BOOK SHELF.

Types of Animal Life. By St. George Mivart, F.R.S. (London: Osgood, McIlvaine and Co., 1893.)

IT is reported of a negro preacher that, having omitted to note the source of his text, he counselled his hearers to search diligently for it, assuring them that in doing so they would find many other texts which would be for their souls' good. We are reminded of this anecdote in reading Prof. Mivart's new book on popular natural history. In our search for the types given in the table of contents we have been rewarded by finding a pleasing description of a goodly number of the higher animals. At the beginning of the fourth chapter we are told that the bull-frog has been selected as one type of animal life in order to introduce the group of *Batrachia*. Very little is said, however, about the bull-frog himself, though there is a figure of him in a deprecating attitude suggestive of some appreciation on the part of the artist of the somewhat shabby treatment this Batrachian elect has received. But there is much interesting matter concerning amphibians of all kinds, illustrated by reference to, or short descriptions of, some twenty genera. The first chapter is headed "Monkeys"; and similar headings would, we think, have been more appropriate throughout. As it is, the animal named is, in each case, merely a convenient starting-point for the consideration of the group to which it belongs. We do not know whether the chapters embodied in the book have already done service in any form in America, but the animals selected suggest that such may have been the case. We have the opossum, the turkey, the bull-frog, the rattlesnake, the Carolina bat, the American bison, the racoon, the sloth, and the sea-lion; while the chapter which deals with, or starts with, the last-named animal begins thus:—"The sea-lion is a beast the sight of which must be familiar to very many Americans." The term "animal life" of the title of the work is shown by the contents to be applied to the dactylate vertebrata only, three-fourths of the volume being devoted to mammals, or beasts as the author prefers to call them.

Unfortunately the proofs have been carelessly corrected, so that misprints (*e.g.* fleshating beasts, p. 209), errors of fact (*e.g.* that *Notoryctes* has recently been discovered in America, p. 60), grammatical errors (*e.g.* only two kinds of elephant now exists, p. 207); a redundant "and" before "which," p. 217), and inelegancies (*e.g.* python-like headed reptiles, p. 149: the blind worm is popularly reported as being deadly poison, p. 146) have been suffered to remain. Technical terms have, as far as possible, been avoided; but it is questionable whether the use of such a term as "wing-wedge bone" is advisable. Surely those who can take in such names of places as "Eschscholtz Bay," and such local names of animals as "Catamiztli," could swallow "alisphenoid" without serious mental indigestion

For the rest we have nothing but praise. A great deal of information is conveyed in a pleasant style. The illustrations, if not quite all that could be desired, are decidedly above the average. The reiterated allusion to the possibly independent origin of similar structures (or the independent origin of different structures, as it appears on p. 120) is, in our opinion, not out of place in such a book. Those who enjoy a smattering of knowledge, picked up from popular works, are apt to be so terribly dogmatic that it is well to urge them to keep their minds "free from prejudice and ready to receive all and any truth which may be demonstrable." C. LL. M.

Science Teaching in Schools. By Dr. Henry Dyer. (London: Blackie and Son, 1893.)

AN address given by Dr. Henry Dyer on science teaching in schools has been amplified and is now published in book form. The points dwelt upon appeal particularly to the managers and teachers of existing elementary schools, and of the secondary and technical schools now being organised in all parts of the country. In an appendix (which, by the way, is almost as long as the address itself) are given syllabuses of elementary science as taught under the London and Leicester School Boards, and the curricula of the evening classes of the Glasgow and West of Scotland Technical College. A commendable feature is the insertion of the courses of instruction at the Ecole de Commerce et de Tissage of Lyons and the Public Mercantile Educational Institute of Leipzig.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE *No notice is taken of anonymous communications.*]

Vectors and Quaternions.

PROF. MACFARLANE claims that his "fundamental rules for vectors are based on physical considerations, the principal one of which is that the square of a vector is essentially positive." His proof is virtually this:—The expression for the kinetic energy ($\frac{1}{2}mv^2$) is an essentially positive quantity. It contains one factor $\frac{1}{2}m$ evidently positive. Hence the other factor v^2 must also be positive. "But v denotes the velocity which is a directed quantity." Unfortunately for this argument v does not denote the velocity in its complete conception—it simply measures the speed. The physicist may think of velocity as being a vector quantity; but in ordinary analysis the vector is not symbolised. We deal only with tensors and scalars. It would be well, I think, if the strict meaning of vector were clearly borne in mind. A vector is a directed line in space, and may be used to symbolise all physical quantities which can be compounded according to the well-known parallelogram law. Displacement is perhaps the simplest conception that can be so symbolised. Velocities, concurrent forces, couples, &c., are in the same sense vector quantities. Now it can be proved rigorously that quadrantal versors are compounded according to this very addition law. On what grounds, then, are they refused admittance to the order of vectors? If a vector cannot be a versor in product combinations, what is the significance of the equation $ij = k$? Regarding this Dr. Macfarlane vouchsafes no remark, save that it is possible to get along without its use. As he himself has not done so, such a possibility lies altogether outside our consideration. Again, I fail to see what "physical considerations" have to do with mathematics of the fourth dimension.

Dr. Macfarlane says that the "*onus probandi* lies on the minus men." To my mind there is no question of proof at all. That the unit vector α should fulfil the equation $\alpha^2 = +1$ is a bare assertion on the part of Dr. Macfarlane and Mr. Heaviside supported by such words as "natural, simple, conventional," and the like. The equation $\alpha^2 = +1$ is a pure assumption, having no better physical basis than the assumption that $\alpha^2 = -1$. *But in quaternions this is not the assumption.* The assumption is—as Dr. Macfarlane admits—that products are to be associative. Hamilton, in fact, invented his calculus so as to have its rules differing *as little as possible* from the recognised rules of algebra. The commutative law had to go, but the others were kept (see *Preface to Lectures*, §§ 50—56). In the system he advocates, Dr. Macfarlane loses the associative principle, and—as I think I show in my paper—gains nothing but a positive sign and an undesirable complexity in transforming by permutations.

As a calculus, quaternions may be developed quite as readily from the conception of the product as from that of the quotient. But in my paper I was arguing against Prof. Gibbs's dictum that the quaternion *as a quantity* corresponded to nothing fundamental in geometry. The extremely simple geometrical conception of a quaternion as a quotient of two vectors sufficiently meets Dr. Macfarlane's query, "Is not the product always the simpler idea?" It is certain that the quotient of any two like quantities has always a meaning; the product is often meaningless.

In the particular geometrical development of quaternions which I indicate in my paper, it can be shown that the quaternion, originally defined as the quotient of two vectors, can also be represented as the *product* (Dr. Macfarlane inadvertently misquotes "quotient") of two quadrantal versors, and this quite independent of the truth that quadrantal versors obey the vector law.

Dr. Macfarlane evidently grudges Prof. Tait (properly, Kelvin and Tait) the use of any but quaternion symbolism. Of course, when $\nabla^2 v$ occurs in ordinary non-quaternion analysis, it is used in the sense of the *tensor*, for only as such can it come in. This surely hardly needed to be pointed out. In quaternions there is no doubt whatever that $\nabla(\nabla\omega) = (\nabla\nabla)\omega = \nabla^2\omega$; and therein, as in all the higher physical applications, the flexibility and power of Hamilton's calculus are at once apparent.

In conclusion, let me say that no reasonable man can possibly object to investigators using any innovations in analysis they may find useful. But in the present case there is a very serious objection to the innovators condemning the system, from which they have one and all drawn inspiration, as "unnatural" and "weak," without in any way showing it so to be. That they can re-cast many quaternion investigations into their own mould does not prove their mould to be superior or even comparable to the original. Yet, in so far as they possess much in common with quaternions, the modified systems used by Gibbs, Heaviside, and Macfarlane cannot fail to have many virtues.

"His form had not yet lost
All her original brightness, nor appeared
Less than Archangel ruined."

Edinburgh University, May 29. C. G. KNOTT.

The Fundamental Axioms of Dynamics.

MY reasons for holding that the fact that potential energy belongs to a system rather than a particle is hostile to the idea of the identity of energy, are briefly these. If two pieces of kinetic energy, are successively transformed and added to a system as potential energy, and then some of the potential energy is retransformed into kinetic, we cannot say *which* of the original kinetic energies thus makes its reappearance; for while both were potential they had no local habitation within the system, and so could not be distinguished from each other.

The objections to including the ether as one of the "bodies" between which contact actions occur, without further explanations, are admirably stated by Prof. Rücker; but I should like to go even further than he does, and point out that if "contact action" means only "action at constant distance" it has not yet been shown how, by such action, kinetic energy comes to be transferred from one body to another. For if the bodies "move over the same distance," and have at any moment the same velocity, their kinetic energies are both increased or decreased *together*; whereas what we wish to show is how that of the one body may increase while that of the other decreases, and why the increase in the one case is equal to the decrease in the other. For example, it may be that in a perfect fluid such transference of kinetic energy actually takes place; but the question is, has Prof. Lodge explained this as a case of "contact action" or "action at constant distance"? What are the things or "bodies" which in this case are actually in contact, and which move over equal distances while the action is going on? Or between what points is the "constant distance" to be measured? Prof. Lodge has not shown in his last paper or in those in the *Phil. Mag.* how "potential energy" can be explained by contact action, nor how kinetic energy can be transferred by contact action alone. But perhaps the answers to these questions are included in the "something more definite" which Prof. Lodge now realises that he has "to say concerning the functions of the ether as regards stress"?

The third paragraph of Prof. Lodge's letter is evidently a joke. I certainly suppose that the denial of action at a distance means that material particles are without *direct* influence upon one another until they touch; *i.e.* that any influence they do exert is *indirect*, and takes place through their both touching something else. Indeed I indicated this in my last letter; but Prof. Lodge apparently hoped I would overlook his omission of the word "direct," and that so the joke would go against me!

EDWARD T. DIXON.

Trinity College, Cambridge, June 10.

Chemical Change.

IN the current number of the Proceedings of the Chemical Society, Prof. H. E. Armstrong publishes two articles on (1) the conditions determinative of chemical change, and (2) the nature of depolarisers. The former deals mainly with the presence of water as a necessary condition of chemical change, the latter with the question of the solution of metals in acids. For some time past I have been engaged with work on the former subject, upon terms of mutual understanding, with my friend Mr. H. B. Baker, whose experiments, following upon those of Prof. H. B. Dixon, have revolutionised our conceptions of chemical change. In the last four years I have also carried on investigations upon the reactions of metals with acids, especially nitric and sulphuric. I should, therefore, propose to deal more fully in a separate publication with the interesting speculations raised by Prof. Armstrong in the articles quoted above. For it has become apparent that after a century of work in chemical science we have no answer to the questions, (1) What is the nature of chemical change? and (2) What is the cause of its commencement? It is probable that both questions resolve themselves, in the long run, into the first. Of facts there is no end, but no interpretation thereof.

The subject is, therefore, ripe for discussion, not only for chemists among themselves, but also, as Prof. Armstrong aptly remarks, for physicists.

Such a discussion might be brought forward at the Chemical Section of the British Association, at Nottingham, in the current year, or, more appropriately, next year in Oxford, the home of Robert Boyle, Mayow, and other earlier chemists.

V. H. VELEY.

The University Museum, Oxford.

Mr. H. O. Forbes's Discoveries in the Chatham Islands.

REFERRING to my former note (*supra*, p. 101) I cannot find that I have been guilty of even "a slight confusion of dates," as Mr. Forbes says (*supra*, p. 126). On his last visit to Cambridge he told me he had forgotten the name I had before written, and asked me to renew my suggestion. I thank him for the kind terms in which he speaks of me, but I must be allowed to disclaim the opinion "that the Chatham Island form was nearer to *Aphanapteryx* than the latter was to *Erythromachus*."

ALFRED NEWTON.

Magdalene College, Cambridge, June 10.

Linnean Society Procedure.

AT the anniversary meeting of the Linnean Society complaint was made that the attendances at the evening meetings were greatly falling off, and fellows were urged to remedy this. The bad attendance is, I think, largely attributable to the lamentably unbusinesslike routine into which the Society's proceedings have fallen, and is not likely to be remedied until *that* is first remedied. Permit me to indicate what appear to me four primary defects in the Society's proceedings.

(1) The actual scientific business of the evening is frequently disposed of in an hour; so that fellows, who attend, sacrifice their evening for very inadequate reward.

(2) In the agenda no intimation is given as to whether the papers to be read will be *really read* by their authors, or whether merely a few sentences will be rattled through by the secretary in order that the paper can be marked as "read." It may thus happen that fellows who attend specially to hear some particular paper read and *discussed* get nothing for their pains. For instance, a short time since, some of us came up specially to hear a paper by Dr. Plowright on the *Aecidiomycetes*, but instead of being treated to a biological paper, followed by a discussion, all that we heard was a few sentences from the introduction read by the secretary! Naturally this sort of thing militates against regular attendances.

(3) Even when an important paper is intended to be read, it may not be reached at all, or if reached may be hurried over and not discussed for want of time. Why is this? Simply because the Society allows "exhibitions" to be intercalated between the formal business and the papers. These exhibitions are often of much interest, often, again, very trivial, but anyhow are quite secondary in importance to the papers, and clearly should be deferred *until the papers* have been disposed of, instead of taking precedence. These exhibitions are not advertised in the diaries of Societies; and it is rather hard that fellows, who have attended to hear an important paper on some new discovery, should go away disappointed because some inconsiderate visitor possibly is allowed to prose about a trifling exhibition for half an hour!

(4) A very grave defect is the confusion of heterogeneous subjects in one evening. If, for instance, alternate meetings were devoted entirely to botanical and zoological papers respectively, probably the attendances would be increased; but the botanists cannot be expected to display much interest in a new genus of earthworms, nor the zoologists in a monograph of *Dianthus*.

If the Council could see their way to adopting these simple reforms that I have suggested, I believe that the attendances would be much increased.

F. H. P. C.

THE GERMAN MATHEMATICAL ASSOCIATION.[1]

THIS is the Catalogue of the Exhibition that was to have been held last year in the picturesque old town of Nürnberg; but in consequence of the state of health in Germany, the meeting of the German Mathematical Association and the exhibition were postponed; and they are now to be carried out this year at Munich, in the month of September.

The last exhibition of a similar kind was that held in London in 1876, the catalogue of which shows that a large collection of apparatus, much of it of a great historical interest, was brought together.

[1] "Catalogue of Mathematical and Mathematico-physical Models, Apparatus, and Instruments." Edited, in conjunction with numerous colleagues, by Walther Dyck. Munich, 1892.

In the present collection the objects of historical interest are comparatively few in number; but, on the other hand, the various models and apparatus intended to illustrate mathematical principles and ideas show what great advances have been made in this branch, so much neglected in our own country.

Prof. Armstrong has recently described in these columns the superiority of the systematic manner in which chemical science is carried out in Germany; and the present Catalogue will show how much we have to learn in the principles of object teaching and illustration in Mathematics.

The Catalogue is divided into two parts. The first part consists of a collection of short and interesting articles.

I. "Geometrical enumeration of the real roots of algebraical equations," by F. Klein, in connection with which No. 47, the plaster model of Sylvester's Amphigenous Surface (constructed by Prof. Henrici) for showing the relations for a quintic equation, may be considered.

II. "Equidistant curve-systems on surfaces," by A. Voss.

III. "Elementary discrimination of singularities of algebraical curves," by A Brill; illustrated by instructive diagrams.

IV. "On the constructive postulates of geometry of space, in their relation to the methods of descriptive geometry," by G. Hauck; an article of great interest to students of Euclid's axioms, and of their modern developments.

V. "Historical studies on the organic description of plane curves, from the earliest times to the end of the eighteenth century," by A. v. Braunmühl; in this article the mechanical methods of the construction of curves, which are perpetually being re-invented, are traced back to their original sources, with interesting historical references.

VI. "On the methods of theoretical Physics," by L. Boltzmann, is a humorous article, describing the former antiquated methods of teaching Natural Philosophy in Germany, apparently not very different to what many of us remember in this country, until Maxwell's vivifying influence made itself felt.

Prof. Boltzmann gives with wonderful clearness Maxwell's ideas about the use of models in Physics; contrasting the views introduced by him with those held before. This article of Prof. Boltzmann is in course of translation and publication by the Physical Society.

VII. "Mechanical integration," by A. Amsler; this gives a complete account of the theoretical principles which underlie the action of Planimeters; it is illustrated with carefully-drawn diagrams.

VIII. "Instruments for Harmonic Analysis," by O. Henrici.

The Catalogue proper begins with the second part; this again is divided into three sections.

The first section contains instruments relating to Arithmetic, Algebra, Theory of Functions, and Integral Calculus, such as Arithmometers, of which the collection and illustrations appear very complete; Galton's Quicunx, illustrating the laws of probability of error; instruments for the solution of equations, Galton's Trace-computer, models of Riemann sheets by Prof. Schwarz, of functions of a complex variable by Prof. Dyck, and a very complete and profusely illustrated collection of Planimeters and Harmonic Analysers of all descriptions. The Rev. F. Bashforth's pioneering description of a Harmonic Analyser, read before the British Association in 1845, deserves especial attention. The elegant little planimeter of Messrs. Hine and Robertson, of New York, might well find a place in the exhibition. In this instrument the record of area is made by the sidelong movement of a sharp-edged wheel on its axle, and not by the rolling motion, so that all slipping of the wheel on the paper is done away with.

The great number of slide-rules is surprising. Mr. Stanley alone has sent more than a dozen.

Among the Arithmometers is the circular form of Mr. Edmondson, and one of great novelty by Prof. Selling, in which the *carrying* is performed continuously and without jerks. The instrument works in consequence with great smoothness and rapidity.

The same section contains instruments and models referring to Geometry, such as angle dividers, ellipsographs, Galton's pantograph, and several perspectographs. Pepys writes in his diary, April 30, 1669 :—"This morning I did visit Mr. Oldenburgh, and did see the instrument for perspective made by Dr. Wren, of which I have one making by Browne ; and the sight of this do please me mightily." If this instrument can be found it would be welcome at Munich ; perhaps Mr. Penrose could help in this matter.

The models for instruction in elementary geometry are very complete, and there are interesting illustrations of polyhedra and space dissection, the subject to which Prof. Alexander Herschel has devoted considerable attention. No. 150 is a collection of six tables on the "Lines of Beauty," to which Hogarth gave great attention ; this exhibit should be of interest to artists.

Under the head of Algebraical Surfaces we find among familiar models a pair of Prof. Henrici's confocal deformable hyperboloids, constructed of a number of straight sticks, tied together at the crossings. Darboux's application of these linked bars to the description of spheres and planes, and the mechanical illustration of the motion of a body under no forces, *à la Poinsot*, noted on p. 327 of the Catalogue, may be instanced here.

The plaster models of the confocal quadric surfaces designed and carried out by Prof. H. A. Schwarz and E. R. Neovius with mathematical accuracy should now form part of the apparatus of every teacher of solid geometry ; the complete series are obtainable for a moderate price through Brill, of Darmstadt.

Surfaces of the third, fourth, and higher degree, Kummer's and Steiner's surfaces, minimum and deformable surfaces, and others too numerous to mention here, are profusely illustrated in the catalogue.

Prof. Dyck's models of surfaces representing the real and imaginary parts of a function of a complex variable at and near a singular value should be studied by every reader of Mr. Forsyth's new book on the Theory of Functions. Of the curious complexity of even the simplest kinds of *essential singularities* a clearer idea is obtained by a glance at these models than by a long study of the analytical expressions.

The third section is devoted to Applied Mathematics, including Mechanics, Mathematical Physics, and instruments required in geodesy and navigation.

The mechanical models illustrate the parallelogram of forces ; the laws of falling bodies, including an arrangement exhibited by Mr. F. R. Barrell of University College, Bristol ; models of Saint Venant's torsion prisms, and so forth.

Mr. A. B. Kempe has supplied a complete account of his Linkages ; and Prof. Reuleaux's well-known collection of kinematical models is profusely illustrated here.

In mathematical physics we find apparatus for the illustration of wave motion and sound vibrations, refraction of light, interference, Mr. Boys's bullet photographs, and Mr. Bashforth's chronograph. Prof. Alexander Herschel's models are given under the head of models of crystalline structure.

Under thermodynamics are found the thermodynamic surfaces of Gibbs and Van der Waals ; and Profs. Oliver Lodge and Fitzgerald exhibit their mechanical illustrations of the laws of electrodynamical action.

Some interesting apparatus are described and illustrated in the last section on geodetic, nautical, and meteorological instruments, including General Strachey's apparatus for the determination of the height and velocity of the clouds.

It would be impossible to give within reasonable limits a detailed account of all the novel and interesting objects described in this catalogue ; but it is hoped that the present short sketch will show that the catalogue itself, apart from the exhibition, is a valuable work of reference, which should be in the hands of all interested in mathematical and mathematico-physical science.

It is expected that the postponement of the meeting to the coming September will give time for the collection of other objects of interest, which can be described and catalogued in an appendix.

A fresh manifesto has been issued by the German Mathematical Association inviting further contributions. Intending exhibitors in this country requiring information and advice, and instructions concerning packing and transport of instruments, are requested to communicate with :—

Prof. O. Henrici, Central Institution, Exhibition Road, W. ; or Prof. A. G. Greenhill, Artillery College, Woolwich.

At the meeting of the Deutsche Mathematiker-Vereinigung at Halle, it was concluded to arrange for an exhibition of models, drawings, apparatus, and instruments, used in pure and applied mathematics, for the occasion of the proposed conference in Nürnberg in the autumn of 1892.

The proposal enjoyed, from the beginning, the support of the Royal Bavarian Government, by which, through special material assistance, as by increased funds which the Imperial Ministry of the Interior liberally provided, the undertaking was assured.

The proposal of the undertaking was received with universal interest in scientific circles, and so the plan of the exhibition seems to be a natural one. A large number of mathematical, physical, mechanical, and geodetic institutes of our own universities and technic high schools, and those outside of Germany, placed the models in the institutes, as well as those of historical interest, to the disposal of the project. Announcements of participation were received from museums, private collections, and individual men of science, at home and abroad.

Besides Germany, America, France, Italy, Austria-Hungary, Holland, Norway, Russia, and Switzerland joined in the project, and especially in Great Britain a committee was composed, with Profs. Lord Kelvin, Greenhill, and Henrici at the head, to send to the exhibition the most prominent articles from the Government, as well as from private collections. Practically all the more important mechanical workshops that are particularly engaged in the production of mathematical apparatus and instruments, and also publishing-houses interested, agreed to share in the scheme.

All initial steps were taken and preparations made. An extensive catalogue was compiled, through the cooperation of numerous men of science, with a minute description and numerous illustrations of the particular objects, together with a series of comprehensive sketches of its contents ; this shows to what extent the various preparations were made.

The condition of the public health of Germany made the postponement of the meeting of the Deutsche Mathematiker-Vereinigung, and consequently the exhibition, which was almost in readiness, inevitable. The directors of the Deutsche Mathematiker-Vereinigung, however, at once concluded to realise their project in 1893.

In Munich, the place selected for the next meeting of the Deutsche Mathematiker-Vereinigung, the extensive rooms of the Polytechnic have already been kindly placed at the disposal of the directors. On account of the proportions that the exhibition has assumed, is will last longer than at first proposed. It will be open from September 1 to 30, as the session of the Mathematical Society, which lasts from September 4 to 10, will be immediately followed by that of the Society of Natural Science in Nürnberg, from September 11 to 15.

In this case, too, we rejoice in the support of the Royal Government, and hearty assurances of intentions to participate in the exhibition have been given by various scientific circles.

Again, therefore, and with confidence, do we turn to our fellow scientific men, to the various mathematical institutes in this and other countries, to publishing-houses and mechanical workshops, with the wish that, through their hearty cooperation, the project may be furthered. We add the plan and more minute information, for the successful realisation of the exhibition.

The exhibition lasts from September 1 to 30, 1893, inclusive, and comprises models, drawings, apparatus, and instruments used in pure and applied mathematics, either for purposes of instruction or investigation.[1]

The Deutsche Mathematiker-Vereinigung will take charge (free of cost) of the fitting of the rooms, the providing of tables, putting in of partitions, &c., as well as the unpacking and repacking of all articles intended for the exhibition. Moreover, the society will assume control of the articles while on exhibition, and will take particular care to preserve them, and will carry an insurance against fire. However, it can assume no responsibility against injury or loss.

Exhibitors who desire their various displays to be exhibited under closed cases must provide them at their own expense.

The expense of shipment to Munich, and, if desired, insurance, must be borne by the exhibitor. For the return the same inducements are held out as last year, viz. free freight over the chief German lines.

A comprehensive detailed catalogue of the mathematical exhibition, according to the announcement made last year, has appeared.[2]

The first part (142 pages) contains a number of essays, of general nature, having reference to problems, results, and methods of presenting geometrical concepts.

The second part (300 pages) contains, according to the suggestion given below, the enumeration and exact description of the articles intended for the Nürnberg exhibition, and gives, with numerous illustrations, a comprehensive view of the general plan of the undertaking, and a statement of what has already been accomplished.

The catalogue will also give the plan of the preparations of the present year; a detailed supplement will be added, in which we hope to perfect the non-completed parts of last year's catalogue.

As far as possible all technical explanations of the articles will be undertaken by the committee.

The committee will attend to all sales and buyings (which are in view by various mathematical institutes of our Hochschulen), and give all desired information.

During the exhibition the sold articles must not be removed from the exhibition rooms, except with special permission of the committee.

The intention to participate in the exhibition may be given by the use of the "Exhibition Announcement" until July 1.

Address: "Herrn Prof. Dr. Walther Dyck,
München, Polytechnicum."

At the same time all papers and scientific notices for the catalogue respecting woodcuts (clichés) for illustration must be sent to the same address.

The editors reserve the right of all abbreviation and change in the notes of Part II. of the catalogue that uniformity may require.

All articles proposed for exhibition must be forwarded from August 15 to 31 under the address: "Mathematische Ausstellung in München (Polytechnicum) zu Handen Herrn Prof. Dr. W. Dyck."

The return of all articles will be effected within two weeks after the close of the exhibition.

In order to more minutely define the extent of the exhibition, we give, in accordance with the arrangement of the catalogue which has already appeared, the following division of groups:—

I.—ANALYSIS.

Calculating apparatus (calculating machines, slide rules); apparatus for the solution of equations and construction of functional relations; models and drawings in algebra and theory of functions; curvometers, planimeters; other instruments for mechanical integration.

II.—GEOMETRY.

Drawing apparatus; models for elementary instruction in plane and solid geometry, trigonometry, and descriptive geometry; polyhedra (division of surfaces and spaces in polygons and polyhedra); analysis situs; plane curves; algebraic surfaces; transcendental surfaces; curves in space and developable surfaces; models in line geometry; models to illustrate theory of curvature; singularities of curves and surfaces.

III.—APPLIED MATHEMATICS.

Mechanics.

Models used in elementary instruction; apparatus and models for the demonstration of the laws and principles of dynamics (equilibrium and movement of a material point; Poinsot motion of a rigid body; apparatus for representing precession and nutation; dynamical tops; gyroscopes; models and articles showing the effect of tension, compression, flexion and torsion of solids; representation of various phenomena in hydro-dynamics); models and apparatus in kinematics with regard to their application in practice.

Mathematical Physics.

Apparatus and models to illustrate the laws of the propagation of waves; models for the explanation of crystal structure; models to illustrate the optical, elastic, and electric properties of crystals; drawings and models in thermodynamics; models and apparatus for the mechanical illustration of electro-dynamic phenomena.

Various Technical Applications.

It is to be understood that exhibitors must declare their willingness to submit to the present rules and further dispositions ordered by the committee for the interest of the exhibition.

For all further information please address the undersigned delegate of the committee. PROF. DR. WALTHER DYCK.

[1] From the field of applied mathematics only those models, apparatus, &c., will be accepted whose chief interest lies in the field of pure mathematics.

[2] The catalogue can be obtained direct from Prof. W. Dyck (München, Polytechnicum) at the price of M. 9.80 (including postage).

RELATIONS BETWEEN THE SURFACE-TENSION AND RELATIVE CONTAMINATION OF WATER SURFACES.

IN a recent paper (NATURE, vol. xlvi., p. 419) I have suggested a method for measuring the relative contamination of an anomalous water-surface in my adjustable trough without fearing an error caused by incomplete separation of the surfaces by the partition. It consists in observing not the displacement of the partition itself, but that of a floating wire laid across the surface, which follows every motion of the superficial water particles.

By this method I have now tried to find a relation between the relative contamination and the decrease of tension which begins at that relative contamination, which we will call unit.

The surface-tension was measured by the separating weight of a ring of thin wire, which had a circumference of 114 mm. and was cleaned by ignition, so that it could be afterwards entirely moistened with water. The ring was attached to a balance with a sliding weight. In this manner the normal surface-tension of water was determined to be 80 mg. per cm. at a temperature of 15° C. The values obtained by experimenters on this subject differing considerably from each other, I shall express the tensions not in absolute measure, but in fractions of the normal surface-tension of water taken as unit. Thus, I found the surface-tension of a saturated solution of camphor 0·72, and that of a strong solution of soap 0·37.

On several occasions, when fast working was required, the tension was not observed directly with the wire-ring, but with the small balance used in my former experiments, the tension corresponding to each separating weight being previously determined by comparison with the large balance.

The observations were made as follows:—A slight trace of oil was communicated to the surface of the trough by means of a wire previously heated to redness, the water-surface still remaining normal. If tallow was to be tried, I left several fragments floating on the water for a short time. When the anomalous surface had reached a sufficient length, the floating wire was put upon it about halfway between the partition and the end of the trough. Then the sliding weight of the balance was displaced successively along intervals of the scale, corresponding to equal differences of tension, and after each displacement one determined the length of surface, at which, under continued contraction, the disk or ring broke off. From these lengths the relative contaminations were afterwards calculated.

Thus I obtained the following results, T denoting relative surface tension and R relative contamination :—

Provence Oil.				Tallow.	
Interval of T. 0·05.		Interval of T. 0·06.			
T.	R.	T.	R.	T.	R.
1·00	0· 1	1·00	0· 1	1·00	0· 1
0·95	1·11	0·94	1·13	0·95	1·12
0·90	1·20	0·88	1·24	0·90	1·22
0·85	1·29	0·82	1·32	0·85	1·31
0·80	4	0·76	10	0·80	1·39
0·75	13	...	...	0·75	6
				0·72	12

It did not influence the results if I used poppy-oil instead of olive-oil, or tallow of various provenience.

The decrease of tension was rapid, and nearly proportional to the increase of relative contamination, till the value 0·82 in the case of oil,[1] or 0·79 in the case of tallow, was attained. At this point a sudden change occurred, and the further sinking took place very slowly. At the same time the "solution current" of floating tallow fragments showed a sudden lessening.

Under continued contraction the water surface at last appeared turbid, and the lowest tension I could attain in this way was about 0·63 with oil and 0·68 with tallow.

The method described is still somewhat imperfect, inasmuch as the water particles in close proximity to the sides of the trough did not participate in the movement of the rest of the surface, indicated by the displacement of the wire-mark. Therefore the results were checked by another method.

The whole surface of the trough was rendered anomalous by means of weak solutions of oil or tallow in benzol, for which purpose 23 drops of the oil solution, or 13 of the stronger tallow solution were required. If the contamination be a little too great, the normal tension may be easily restored by immersing small strips of paper. Then part of the surface was cleansed by shifting the partition from the end towards the middle of the trough about 10 cm., and one drop of the solution being evaporated on the newly-formed surface, the partition was removed and the ten-ion measured. The increase of relative contamination thus added by each drop was respectively $\frac{1}{23}$ and $\frac{1}{13}$. The means of all observations made in this manner were as follows :—

Provence Oil.		Tallow.	
R.	T.	R.	T.
0·0000	1·000	0·000	1·000
1·0000	1·000	1·000	1·000
0·0434	0·973	1·077	0·963
1·0868	0·945	1·154	0·924
1·1321	0·916	1·231	0·879
1·1736	0·891	1·308	0·832
1·2170	0·860	1·385	0·790
1·2604	0·834	1·462	0·790
1·3038	0·815	...	...
1·3472	0·815	2	0·782
...	...	4	0·760
2	0·805		
4	0·795		
12	0·760		

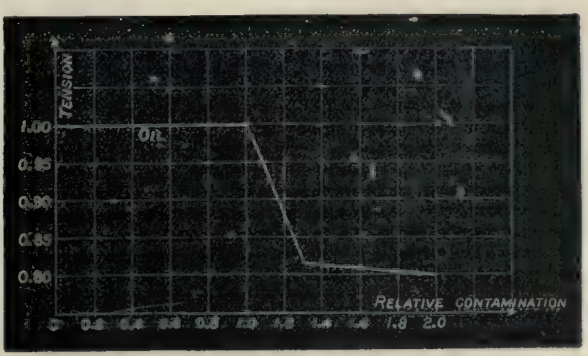
[1] When ordinary olive-oil was used the value in question was 0·78.

The results agree tolerably well with those obtained by the first method, and show still more clearly, that the tension in the beginning of the anomalous state may be approximately expressed by

$$T_0 - T = k(R - 1),$$

T_0 denoting the normal surface-tension and k a constant which is, in the case of oil, 0·60, and in the case of tallow, 0·54.

The course of the tension of a surface contaminated by oil may be more clearly seen from the following curve :

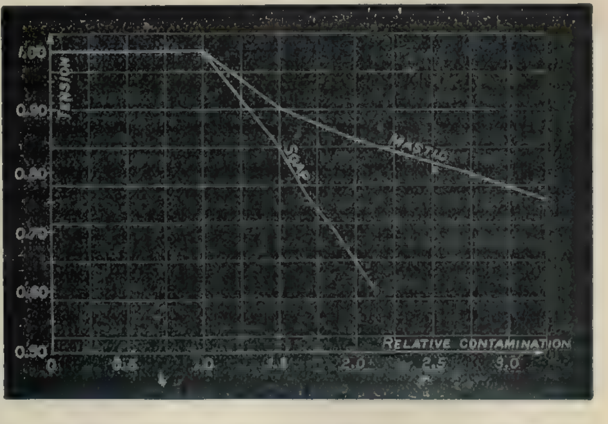


When the water-surface is not contaminated by pure grease, but by any other substance, as soap, resin, palmitic acid, the tension behaves quite differently.

If the justly anomalous surface be contracted, the tension at first sinks rapidly, but gradually begins to rise again, while the area of the surface remains constant; the latter being re-extended, the normal condition is attained at a shorter surface than before contraction. When the surface then is left for some time in the normal state, the length of the anomalous surface increases again.

Therefore the difference of tension produced by varying the area in a given ratio depends very much upon the time required for the contraction or extension.

The deeper the tension is lowered the stronger becomes its tendency to rise, till at last a further sinking



only can be observed during the motion of the partition, and this even is the case with grease at higher degrees of contamination. A sudden change of direction at a certain lowered tension I could perceive in no other curve than that of pure grease. As an example may be exhibited the curves of soap and mastic, when the contraction was as quick as possible. Mastic was introduced by means of benzol, soap directly by contact.

On strongly contracted surfaces, every substance gives a stiff, visible pellicle, composed, as it appears, of small incoherent particles.

Certain peculiarities of some substances still must be mentioned.

(1) The contamination due to colophony and palmitic acid continually diminishes, and at last seems to disappear altogether on standing, which is not the case with mastic.

(2) On the other hand, if the surface has been for a moment in contact with a piece of soap, the contamination continues to increase after the removal of the soap.

(3) Stearic acid renders the water surface stiff as soon as the tension begins to sink.

(4) A surface made anomalous by olive-oil in the course of twenty-four hours undergoes a change, by which the curve of tension is totally altered.

On the whole the phenomena are rather complicated, the tension by no means being determined by the quantity of contaminating substance in the unit of area; but depending considerably upon conditions that are still to be investigated. Especially in the experiments relative to the final tensions attainable by the various substances in the state of utmost concentration I could not succeed in getting definite results.

AGNES POCKELS.

NOTES.

A BRONZE statue of Arago, erected in the grounds behind the Paris Observatory, was unveiled by M. Poincaré on Sunday last in the presence of several members of the Institute, the observatory officials, and a few spectators. This is the third monument that has been erected to the memory of that renowned astronomer.

PROF. MAX MÜLLER has had the order of Medjidieh conferred on him by the Sultan of Turkey. This is a graceful recognition of Prof. Müller's scientific researches.

BARON VON NORDENSKJÖLD, of Stockholm, has been elected a Foreign Member of the Paris Academy of Sciences.

DR. E. B. TYLER, Curator of the Oxford University Museum, has been elected an Associate of the Brussels Academy of Sciences.

THE announcement that Mr. E. B. Poulton, F.R.S., has been appointed Hope Professor in succession to the late Prof. Westwood will be received with satisfaction by all naturalists who are familiar with this author's work. For more than ten years Mr. Poulton has displayed the greatest activity as an original investigator, more especially in connection with the subject of insect colouration, which he has advanced by many important discoveries. His contributions to insect morphology are sufficient guarantee that the purely systematic side of entomology will not be neglected at Oxford. All who are interested in the status of the University as a centre of biological research will recognise the wisdom of the electors in making their selection.

IN the House of Commons on June 8 Mr. Rentoul asked the Secretary of State for War whether he was aware that at the recent Staff College examination there was a striking change, of which no notice had been given, in the nature and scope of the mathematical examination; and whether steps would be taken to prevent any of the officers who were candidates at the examination being disqualified in consequence of this unusual procedure. Mr. Campbell-Bannerman replied that the change was due to the appointment of a new examiner, and said that, as the examination is competitive, the candidates would not be put to any disadvantage by the greater difficulty of the questions. This may be a sufficient explanation of the circumstance, but, in many cases, candidates for Government appointments have found upon reading the question paper, that important changes have been made in the character of the examination without any intimation whatever having been given to them.

A *conversazione* of the Institution of Electrical Engineers will be held in the galleries of the Royal Institute of Painters in Water Colours on Friday evening, June 23.

THE Selborne Society have made arrangements for a visit to Selborne, the home of Gilbert White, on Saturday, June 24. Lord Selborne will occupy the chair at lunch, and be supported by Lord Northbrook, the Earl of Stamford, and Sir John Lubbock, Bart. Tickets for the excursion can be had from the Secretary, 9, Adam Street, Adelphi, W.C.

THE fourth annual meeting of the Museums' Association will be held in the rooms of the Zoological Society during the first week in July. The formal proceedings will commence on Monday, July 3, at 8.30 p.m., when Sir W. H. Flower, F.R.S., the President-Elect, will deliver an address. It is proposed to devote mornings to the reading and discussion of papers bearing upon the subject of museums, and in the afternoons and evenings visits will be made to various Metropolitan museums. The arrangements of the meeting will be greatly facilitated if those who propose to attend will give early notice to Mr. F. W. Rudler, 28, Jermyn Street, S.W.

THE fifth summer assembly of the National Home Reading Union will be held at Ilkley, Yorkshire, from July 1 to July 8. The inaugural address will be delivered by the Master of Trinity College, Cambridge, and there will be lectures by Mrs. Henry Fawcett, Prof. Michael Foster, Sir Robert Ball, Mr. W. G. Collingwood, Mr. Churton Collins, and others. Short lectures on archæology, botany, and geology will be given each day, and will be followed by excursions to places of interest in the neighbourhood. There could hardly be a more pleasant road to knowledge than that afforded by such a meeting as this.

VARIOUS learned and scientific bodies of Liverpool and the district, being desirous of inviting the British Association to meet at Liverpool in 1896, sent representatives to the Mayor on June 5 for the purpose of soliciting his aid in the furtherance of their object. The Mayor would not pledge himself to any course of action, but said he would consult the Corporation upon the matter.

THE Permanent Committee of the International Congress of Zoology propose, as the subject for the S. A. I. le Tsarévitch prize, the study of the fauna of one of the great regions of the globe and the relations between this fauna and that of neighbouring regions. The award will be made at the Leyden Congress in 1895. By the rules of the Congress this prize cannot be given to a Dutch man of science. The jury will accept works bearing upon a branch or a class of the animal kingdom. Manuscripts or printed papers should be written in French and sent, before May 1, 1895, to M. le Président du Comité permanent, Société Zoologique de France, 7 Rue des Grands-Augustins, Paris.

WITH the exception of heavy thunderstorms which occurred in the central part of Ireland during the night of Friday, the 9th inst., in which 1·2 inch of rain fell, and in Merioneth the next day, the weather, as represented by the stations reporting to the Meteorological Office, has been practically rainless over nearly the whole of the British Islands. These conditions were owing to the persistence of an anticyclone over Scandinavia, the North Sea and our own area. The temperature has been somewhat high for the time of year, the highest daily maxima in the south and west having at times exceeded 75°; but in the north, and especially on the east coast, owing to the continuance of easterly winds, many of the maximum readings have been below 60°. During the early part of the present week the anticyclone decreased in intensity and began to move slowly eastward, while a depression which lay over the south-west of France moved northward, causing the barometer to fall generally over our islands, and on Tuesday night, the 13th inst., a thunderstorm occurred at Jersey, while a further rise of temperature occurred over the southern portion of the kingdom, the maximum at Cambridge reaching 81°. The *Weekly Weather Report* of the 10th inst. showed that the greatest excess of temperature occurred in Ireland and the Channel Islands, where it was 5° above the mean. The rainfall just equalled the mean in the east of Scotland and the north of Ireland only. Bright sunshine was above the usual amount everywhere; the percentage of duration ranged from 29 to 38 in Scotland, from 36 to 40 in Ireland, and from 40 to 67 over England, while in the Channel Islands the percentage was as high as 75 of the possible amount.

WE are indebted to Dr. A. Buchan for the discussion and publication (in vol. ix. of the Journal of the Scottish Meteorological Society) of a very valuable series of mean monthly and yearly temperatures for London and vicinity for 130 years, from 1763 to 1892. The only interruptions of the continuity of this long series occurred in May 1777 and July 1780, and the means for these months have been interpolated. For the 130 years the mean temperature of London is 50°·2. The highest mean temperature of any month was 74°·1 in July 1783, and the lowest 25°·9 in January 1795, the difference being 48°·2. The warmest seasons were, winter, 1779, 8°·3 above the normal value; spring, 1811, +5°·2; summer, 1783, +8°·2; and autumn, 1777, +5°·1. The coldest seasons were, winter, 1814, 6°·5 below the normal; spring, 1837, −6°·7; summer, 1816, −4°·6; and autumn, 1877, −4°·1. The year 1783 had the highest mean annual temperature, being 5°·2 above the normal for the year; and 1816, the lowest, being 3°·5 under the normal. Dr. Buchan states that much labour has been spent in searching for evidence of cycles, but that it cannot be said that the results show more than highly interesting resemblances and contrasts among the months, and that in whatever way the periods are viewed, they suggest no appearance of a cycle. But a tendency is shown of types of high and low temperature to prolong themselves during months, seasons, and years. Following this paper is an equally important discussion by the same author of the temperature of the north-east of Scotland for 129 years, from 1764 to 1892, from observations taken at Gordon Castle and other places.

AT the instance of Herr von Helmholtz, and with the support of the Berlin Academy of Sciences, Drs. Franz Richarz and Otto Krigar-Menzel have undertaken a remarkable series of experiments for the purpose of determining by weighing the diminution of gravity as we ascend from the surface of the earth. The method was theoretically the following:—To each pan of an ordinary balance is attached another pan by means of a rod about 2 m. long. Two sensibly equal masses are placed in the left upper and the right lower pan respectively. The gravitational attraction being stronger on the latter weight, a difference will be indicated by the balance. On removing the left weight from the upper to the lower pan, and the right weight from the lower to the upper, the difference acts in the opposite direction, and half the mean of the two differences gives the decrease of gravity with the height. It is almost needless to say that the experiment was one of very great delicacy and difficulty. It was performed in an earth-covered casemate of the citadel of Spandau, partly in order to utilise a mass of lead weighing about a hundred tons to determine the attraction exerted by it. The necessary preparations were begun in 1887, and the main part of the observations has only just been concluded. The difference between the values of g at two points, one 2·26 m. above the other, was found to be $6{\cdot}523 \times 10^{-6}$. The calculated value was $6{\cdot}970 \times 10^{-6}$. The difference may be due to a density of the strata below the station being less than the average.

A THERMOSTAT for the comparison of standard thermometers between the temperatures of 50° and 300° C. is described by Herr A. Mahlke in the current number of the *Zeitschrift für Instrumentenkunde*. It is used at the Physikalisch-Technische Reichsanstalt for the purpose of maintaining the thermometers to be compared at certain temperatures for which the boiling point of some substance is not available. It consists essentially of an oil-bath in a copper cylinder surrounded by another copper cylinder, the space between the two being filled with air. Heat is applied to the outer vessel. The heated air warms the inner vessel by circulating round it, there being a clearance of 2 or 3 cm. all round. Special precautions are taken to keep the level of the oil in the inner vessel constant, and the temperature of the oil uniform throughout. Both cylinders are closed with lids containing holes through which to insert the thermometers. The oil is kept circulating by means of two propellers enclosed in vertical copper cylinders open at both ends. Their axes project through the outer lid, and are provided with pulleys rotated by means of a small water motor. The whole arrangement is designed to keep the entire body of oil in motion, so as to prevent unequal heating. Surplus oil, due to expansion, and any oil-vapour that may be evolved, are drawn off through a siphon leading through the walls of the cylinders into a refrigerator. The apparatus has worked very well, the variations of temperature not exceeding the average errors in reading the thermometer scales.

THE extremely high cost of high resistances made of metallic wire causes the discovery of a cheap substitute to be a matter of considerable importance. Most of the substitutes hitherto proposed, such as liquid resistances, pencil marks on glass or ebonite, &c., are subject to the objection that they have an extremely high temperature coefficient, and in the case of the pencil mark, on account of the extreme thinness of the conducting material, the rubbing off of a few particles causes a great increase of resistance. These resistances also depend in a considerable degree on the electromotive force to which they are subjected. The *Elettricista* for May contains the description of a new material for the construction of high resistances, discovered by E. Jona which is said to be free from most of these defects. He uses an ebonite tube which is filled with a mixture of graphite and unvulcanised ebonite in suitable proportions. The mixture is then vulcanised, when it hardens and adheres to the containing tube. Metal cups fitted with binding screws are fixed to the ends. In this way a resistance of a megohm can easily be obtained in a tube 10 cm. long and of 15 mm. diameter.

IN a recently-published number of the proceedings of the Cambridge Philosophical Society there is an interesting paper by Messrs. Griffiths and Clark on the determination of low temperatures by means of platinum thermometers. Acting on the suggestion of Profs. Dewar and Fleming, that from observations on the resistance of certain pure metals (including platinum) at very low temperatures, it would appear as if the resistance vanished at absolute zero, the authors have calculated by means of Callendar and Griffiths' method the temperature at which the resistance of several platinum thermometers, whose accuracy had been severely tested, would be zero. The values obtained seemed to corroborate the conclusions arrived at by Profs. Dewar and Fleming as the mean value found for the temperature at which the resistance would be zero is −273°·96. This gives a convenient method of graduating a platinum thermometer, when a high order of accuracy is unnecessary, without the usual observation in sulphur vapour, which, in the absence of special apparatus, is a troublesome operation. For if the platinum is pure, it may be assumed that at absolute zero the resistance vanishes, and thus a measure of the resistance in steam and ice will allow of its constants being calculated.

While making the observations mentioned in the previous note the authors were led to suspect that the heating effect of the small currents necessary to measure a resistance are of more importance than is usually supposed. During their determination of the value of the mechanical equivalent of heat by means of an electric current, they measured the temperature of the bath containing the wire under experiment, at which the resistance was the same, while the difference of potential at the ends was increased from one to ten volts. Hence they were able to calculate the change of resistance (δR), and the results seem to show that $\delta R = aC^2$ where a is a coefficient depending on the nature of the surroundings. Thus, by determining the resistance of a coil with two different electromotive forces, it would be possible to find the value of a, and hence calculate the value of the resistance when $C = 0$.

The June number of the Journal of the Institution of Electrical Engineers contains a long paper by Mr. A. T. Snell on the distribution of power by alternate current motors. The paper is followed by a full report of the discussion which it raised when it was communicated to the Institution.

According to the *Electrical Review* Messrs. Cross and Mansfield have recently contributed to the Massachusetts Institute of Technology some further experiments on the excursion of the diaphragms of telephones. They find that on increasing the magnetising current, the corresponding permanent deflection increases more and more rapidly in proportion up to about $\frac{3}{10}$ths of an ampère, after which the deflection is very nearly proportional to the current. Similarly the results show that as the strength of the magnet of the telephone increases, the amplitude of the vibration likewise increases up to a certain limit and then falls off. The maximum motion of the diaphragm for a given value of the alternating line current employed is attained before the core reaches half saturation. It also appears that, in general, the amplitude of vibration of the diaphragm increases less rapidly than the current actuating the telephone.

Agriculture is rapidly becoming more scientific. In France the Société Nationale d'Agriculture lately charged a special commission to study the question of agronomic maps, designed to afford the farmer useful indications on the physical and chemical qualities of land, so that he may know how to improve it, what manures to apply, and in what quantity, &c. In an interesting report on behalf of this commission (summarised in *Rev. Gen. de Sciences*) M. Carnot represents that the time is now ripe for production of cantonal and communal agronomic maps, on a large scale; and a number of suggestions are offered as to how the work should be done.

There is now a general tendency in Russia to introduce some teaching in agriculture and horticulture into the primary schools. Both private persons and the Provincial authorities freely give grants of land to the schools and to the teachers' seminaries for their fields and orchards, and in many schools the plots of arable land and gardens attended to by the pupils become small centres of agricultural and horticultural education. In Caucasia the same tendency is even more pronounced, and no better idea can be given of the extent of this new movement than by giving the following facts relative to the primary schools of Kuban, a province of Northern Caucasia. This year ten schoolmasters have been invited to attend the lectures upon sericulture and bee-keeping at the schools of the Cossack villages, Armavir and Labinskaya. The inspector of the schools has acquired, with the modest grant of £35, thirty appliances for raising silkworms, and five arrangements for each school for pumping out honey from the beehives, and preparing the artificial wax honeycombs; in addition to which, ten schools have been supplied with apparatus for silkworm culture, while others have been supplied with seeds of plants of special use to bees. All schools which have gardens of silkworm trees have been supplied with seeds of the tree, and 20,000 young trees have been distributed among them. Fourteen schools are expected this year to carry on the silkworm culture, and ten other schools are already carrying on experiments relative to the same.

In the current number of the *Entomologists' Monthly Magazine*, Mr. R. McLachlan, F.R.S., in an article on the extinction of several species of British butterflies within recent years, and the decadence that appears to be going on with respect to others, suggests the enforcement of a close-time to last continuously during the whole of a series of five or ten years.

In a recent paper to a Christiania journal on the melting of inland ice (whereby glaciers are prevented from growing indefinitely in thickness, notwithstanding additions above the snow line), Herr Schiotz attempts to estimate the three factors concerned in the interior fusion, viz. earth heat, friction, and pressure, and arrives at the result that a more important agent than any of these (in hindering glacier growth) is solar heat melting the surface ice below the snow line (*Naturw. Rdsch.*, No. 21).

A paragraph describing a supposed earthquake felt in the Isle of Man on the afternoon of May 5 was published in several London and provincial papers. Mr. Charles Davison writes us to the effect that his inquiries show that the shocks were due, not to earthquakes, but to the firing of heavy guns from a battleship situated near the island.

During the cutting of a tunnel at the Notabile Terminus of the Malta Railway (writes Mr. N. Tagliaferro in the *Mediterranean Naturalist*) a piece of lignite, of dimensions about 11 by 4 by 1 inches, was found embedded in the blue variety of the upper globigerina limestone. The upper layers of this limestone appear to be contemporaneous with the Langhian series of the miocene beds of Italy, and were probably deposited on an ascending sea-floor at a depth of nearly 300 fathoms. The discovery of lignite in these beds is, therefore, of some importance.

Writing in *Science* of May 5, Dr. Morris Gibbs says that the results of observations of the songs of fifty different species of birds shows that the notes do not change in quality as a result of change in emotion. After robbing nests he has waited and listened, allowing ample time for the male to learn of the spoliation. In each instance the male, upon returning to the empty nest, at once burst into song, and though it is possible that the song expressed much sorrow or complaint, Dr. Gibbs could never distinguish any difference between it and the warbling he was accustomed to hear.

In the *Lancet* of June 10, Dr. Edwin Haward calls attention to a point with respect to proofs of death, which, in consequence of the growth of opinion in favour of cremation, is of great importance. Sir B. W. Richardson and himself had to decide in a particular case whether life was or was not extinct. Of ten tests applied to the body, eight indicated that death was complete. These were (1) heart sounds and motion entirely absent, together with all pulse movement; (2) respiratory sounds and movements entirely absent; (3) temperature of the body the same as that of the surrounding air in the room; (4) a bright needle plunged into the body of the biceps muscle and left there showed no sign of oxidation on withdrawal; (5) intermittent shocks of electricity passed through various muscles and groups of muscles gave no indication whatever of irritability;

(6) the fillet test applied to the veins of the arm caused no filling of veins on the distal side of the fillet; (7) the subcutaneous injection of ammonia caused the dirty brown stain indicative of dissolution; (8) rigor mortis was detected on making careful movements of the joints of the extremities and of the lower jaw. Two tests, however, indicated that life was not extinct. The opening of a vein to ascertain whether the blood had undergone coagulation showed that the blood was fluid. This is not very important, because under abnormal conditions the blood may remain fluid after death has occurred. But a criterion which has been believed to afford sure evidence of life or death was found to fail. It is known as the diaphanous test, and consists in holding the fingers of the supposed dead person in front of a strong light, and looking through the narrow spaces between two fingers just touching one another. The belief has been that if the person is alive a line of scarlet colour will be seen, and that the absence of the colour indicates death. In the case investigated, however, the scarlet line of light between the fingers was clearly visible, though death was assured by the fact that decomposition set in. Further, Sir B. W. Richardson records a case in which the test, applied to the hand of a lady who had simply fainted, gave no evidence of the scarlet line; so that, on that test alone, she would have been declared dead. Thus the diaphanous test, which has been considered by many as infallible, has been proved to be untrustworthy.

HERRN FRIEDLÄNDER UND SOHN, of Berlin, have issued their *Natural History News*, Nos. 3–9. The lists contain advertisements of recent literature on natural history.

THE Technical Instruction Committee of the Essex County Council have just issued a prospectus containing syllabuses of lectures on chemistry and biology—sciences which are specially applicable to the industries of the county.

Iron has ceased to exist as an independent journal, after living for twenty years under that title and fifty years as the *Mechanics' Magazine*. It has been amalgamated with *Industries*, and the combined journal will in future be issued under the title of *Industries and Iron*.

THE life of Sir Richard Francis Burton, by Lady Burton, will shortly be published by Messrs. Chapman and Hall. The work will recount Sir Richard's life from his birth to his death, and will comprise two volumes of about 600 pages each. A large amount of space is devoted to a description of his explorations.

WE have received the New South Wales Statistical Register for 1891 and previous years, compiled from official returns by Mr. T. A. Coghlan. The volume is a collection of eight parts which have already been issued separately. It is wholly devoted to statistics.

FROM Felix Alcan, of Paris, comes a work on the "Conquête du Monde Végétal," by Louis Bourdeau. The arrangement of the matter in the book is very good. After discussing the general theory of the growth of plants, the author passes to the study of various groups of plants of economic and of ornamental value. This branch of the subject is divided into seven parts. The operations of culture furnish matter for a special chapter, and the book is concluded with an account of the creation and preservation of artificial varieties of some types of plants. To a large extent the subject is treated historically.

THE Life Saving Society has for its chief object the development of instruction in such swimming arts as would be of assistance to a person endeavouring to save life. They have just issued a revised edition of an excellent little handbook in which an account is given of the methods recommended by the society for the rescue of the drowning and the resuscitation of the apparently drowned. It is hoped that the issue of this course of instruction will lead to the subject of life-saving and resuscitation being included in the curriculum of every school.

THE decomposition of steam by means of heated magnesium makes, according to Herr Rosenfeld (*Berichte*), a pretty lecture experiment. A short piece of a combustion tube is furnished at one end with a stopper and tube for escape of gas, and connected at the other with a vessel containing water. A little powdered magnesium (0·5 to 1 gramme) is put in the tube, and cautiously heated; then, by gently heating the water, steam passes over, and the metal merely glows. In this way is obtained a steady current of hydrogen, which can be collected over water. But if a rapid current of steam is sent over the heated metal, the latter burns with dazzling light, and the heat breaks the tube. This occurs, however, only after some time, when a good deal of hydrogen has been collected in the bell-jar.

AN interesting compound of aluminium chloride with benzoyl chloride, the chloride of the benzoic acid radicle, has been obtained in large crystals by M. Perrier, and an account of it is contributed to the current number of the *Comptes Rendus*. Such compounds are of particular importance in view of the remarkable *rôle* which aluminium chloride has been found to play in synthetical chemistry, as affording some insight into the nature of the intermediate reactions upon which the apparently catalytic action of this useful salt depends. The new compound now described is represented by the formula $C_6H_5COCl.AlCl_3$, or, if aluminium chloride is considered as represented by the usual double formula, $(C_6H_5COCl)_2.Al_2Cl_6$. It is readily prepared by heating about ten grams of benzoyl chloride dissolved in 150 c.c. of carbon bisulphide with nine grams of anhydrous aluminium chloride in a flask fitted with a reflux condenser. After three hours' ebullition and subsequent cooling a large yield of the colourless tabular crystals of the new compound is obtained. The crystals decompose somewhat rapidly in moist air, and they are instantly decomposed by water, forming an aqueous solution of aluminium chloride, hydrochloric acid, and benzoic acid. They are readily soluble, however, without decomposition, in carbon bisulphide. The formation of compounds of this nature is not confined to the chloride of benzoic acid, but would appear to be general throughout the aromatic series, and M. Perrier has already isolated in a pure state the corresponding compound containing the chloride of phthalic acid. Moreover, in the fatty series the chloride of butyric acid is found to combine readily with aluminium chloride, in carbon bisulphide solution, to form a compound of the same definite nature.

THESE compounds are not the first of the kind that have been prepared. Last year MM. Perrier and Louise described a considerable number containing the aromatic ketones, ethers, and phenols. They were all constituted upon the same type, $M_2.Al_2Cl_6$, where M represents a molecule of a ketone, ether, or phenol. The compound containing acetophenone, for instance, $(C_6H_5.CO.CH_3)_2.Al_2Cl_6$, may be obtained in good crystals by cooling the liquid formed by heating acetophenone dissolved in carbon bisulphide with aluminium chloride to 40°. Similarly the compound with phenyl benzoate, $(C_6H_5.COOC_6H_5)_2.Al_2Cl_6$, crystallises from the liquid obtained by heating the components in carbon bisulphide solution. They are all of the same character, permanent in carbon bisulphide solution or in dry air, but decomposed rapidly by moisture.

THE formation of the above compounds explains at once the important synthetical method introduced by MM. Friedel and Crafts for the preparation of the aromatic ketones by the action of the hydrocarbons upon the chlorides of the acid radicles in presence of aluminium chloride. It is most probable that a compound of aluminium chloride with the chloride of the acid radicle, $(R.COCl)_2.Al_2Cl_6$, is first formed, and that this is subsequently converted by the hydrocarbon into the compound of aluminium chloride and the ketone, $(R.CO.R)_2.Al_2Cl_6$, with elimination of hydrochloric acid. Under the conditions of the experiment this latter compound is dissociated into free aluminium chloride and the free ketone. That this explanation is very near the truth is demonstrated by the fact that by working in carbon bisulphide solution, M. Perrier has actually converted his new compound with benzoyl chloride, $(C_6H_5COCl)_2.Al_2Cl_6$, directly into the ketone compound, $(C_6H_5.CO.C_6H_5)_2.Al_2Cl_6$, by reacting upon it with benzene. The crystals of the ketone compound obtained were identical with those prepared from benzophenone itself.

WE regret that in announcing the birthday honours last week the name of Mr. Daniel Morris was printed "Mr. David Morris."

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include the Actinian *Chitonactis coronata*, the Polychæta *Glycera capitata* and *Proceræa picta*, the Opisthobranchs *Candiella plebeia* and *Triopa claviger*, the Schizopod *Leptomysis mediterranea*, the Ascidian *Pycnoclavella aurilucens* and a number of *Amphioxus lanceolatus*. The character of the floating fauna has exhibited little change since the preceding week, Ctenophora and Leptomedusæ having been especially abundant. The following animals are now breeding: Various Serpulidæ, the Schizopoda *Schistomysis arenosa* and *Leptomysis mediterranea*, the Decapod *Crangon sculptus*, and the Ascidian *Botryllus violaceus*. The majority of *Amphioxus* also are full-grown and mature.

THE additions to the Zoological Society's Gardens during the past week include a Stair's Monkey (*Cercopithecus stairsi*, ♂) from East Africa, presented by Mr. F. Hintze; a Himalayan Bear (*Ursus tibetanus*, ♂) from Northern India, presented by Capt. Michael Hughes, 2nd Life Guards; a Maugé's Dasyure (*Dasyurus maugæi*) from Australia, presented by Mr. Robert Hoade; four South Island Robins (*Miro albifrons*) from New Zealand, presented by Capt. Edgar J. Evans; two Carrion Crows (*Corvus corone*), British, presented by the Hon. Wm. Edwardes; a Rose-crested Cockatoo (*Cacatua moluccensis*) from Moluccas, presented by Mr. J. B. Sutherland; a Herring Gull (*Larus argentatus*) British, presented by Miss M. A. Croxford; a Long-eared Owl (*Asio otus*), a Tawny Owl (*Syrnium aluco*), British, presented by Mr. Alan F. Crossman; two Horned Lizards (*Phrynosoma cornutum*) from Texas, presented by Mr. A. E. Jamrach; a Red-handed Tamarin (*Midas rufimanus*) from Surinam, a Yellow-footed Rock Kangaroo (*Petrogale xanthopus*, ♂) from South Australia, fourteen Horned Lizards (*Phrynosoma cornutum*) from Texas, four Tuberculated Iguanas (*Iguana tuberculata*) from the West Indies, deposited; a Malbrouck Monkey (*Cercopithecus cynosurus*) from West Africa, four Bronze-winged Pigeons (*Phaps chalcoptera*), two Australian Sheldrakes (*Tadorna tadornoides*, ♂ ♀) from Australia, four Green Waxbills (*Estrelda formosa*) from India, purchased; a Vervet Monkey (*Cercopithecus lalandii*), a Japanese Deer (*Cervus sika*, ♀) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

FINLAY'S COMET (1886 VII.).—The ephemeris of Finlay's comet for this week is as follows:—

12h. *M.T. Paris.*

1893.		R.A. (app.) h. m. s.		Decl. (app.) ° ′
June 15	...	1 45 47	...	+ 8 2 9

DETERMINATIONS OF GRAVITY.—The Appendix (No. 15) of the report of the "United States Coast and Geodetic Survey for 1891" contains a set of determinations of gravity made with half-second pendulums on the Pacific coast, in Alaska, and at Washington, D.C., and Hoboken, N.J., under the superintendence of Mr. T. C. Mendenhall. On account of the difficulty and cost of a previous undertaking, the apparatus in the present determinations has been greatly reduced both in magnitude and complexity by using a pendulum vibrating to half a second and a chronometer in place of a clock. The pendulum apparatus consisted of a set of three-quarter metre pendulums, a dummy or temperature pendulum, an air-tight receiver in which the pendulums were swung, a flash apparatus, wherein an electromagnet in the circuit of a chronometer moves a shutter and throws out a flash of light each second, a telescope for observing, mounted above the flash-light apparatus and various accessories. The pendulums themselves constituted a set of three, so that discrepancies in any one of them, if they appeared, could easily be detected. Each was composed of an alloy of aluminium 10 per cent. and copper 90 per cent., a composition highly resistible to corrosion. The base station adopted was at the Smithsonian Institution in Washington, and the value assumed there for g was 980·10 dynes.

The following are the values of g as obtained at five places, a table given here including several other determinations:—

Station.	Lat. N. ° ′	Long. W. of Greenw. ° ′	Elev. above sea-level. Feet.	g at station. Dynes.	g reduced to sea-level. Dynes.
Washington, D.C.	38 53	77 02	34	[980·1000]	980·1020
San Francisco, Cal.	37 47	122 26	375	979·9507	979·9727
Seattle, Wash.	47 36	121 20	243	980·7116	980·7258
Mount Hamilton, Cal. Lick Observatory	37 20	121 39	4205	979·6456	979·8920
Hoboken, N.J.	40 44	74 02	35	980·2555	980·2576

SOLAR OBSERVATIONS AT THE ROYAL COLLEGE, ROME.—In the *Memorie della Società degli Spettroscopisti Italiani* Prof. Tachini communicates the observations of the sun made at the Royal College Observatory during the first trimestre of this year. The records of the protuberances during this period show that the monthly numbers were 138, 198, 264, a rapid increase, as will be noticed, the maxima heights being 1026″, 1149″, and 1650″ respectively for the same months. The mean altitudes increased also rather irregularly, 706″, 824″, and 1103″ being the numbers given. With regard to the spots, March contained the most numerous (358), being 94 more than January and 73 more than February. The number of groups for the first two months were, curiously enough, nearly equal (the numbers being 101 and 102), but the extensions were very different, 1968 and 2215 representing the numbers for the spots, and 870 and 1170 for the faculæ. The same number of these memoirs gives a summation of the solar observations made at the Royal Observatory at Palermo during the year 1892 by M. T. Lona and A. Mascari, and M. Abetti's observations of the conjunction of Mars with υ Tauri, and of Saturn with γ Virginis.

L'ASTRONOMIE FOR JUNE.—The opening article in this month's number contains a description of a very remarkable observation on Jupiter made by M. Lumsden on September 20, 1891. It seems that he has seen the shadow of the first satellite of Jupiter on the planet's surface, accompanied and followed by a second shadow, not so dark and sharp as the original satellite, but nevertheless very distinct and incontestable. This second shadow is said to have moved uniformly with the real one, following it at an equal distance. The observer seems to be very certain that it was not a spot, so the question is—How can this secondary shadow be explained? It was thought at first that as the other satellites were all on the same side of the primary it might have been one of their shadows, but the facts show that that was not the case. M. Lumsden suggested that perhaps it was the shadow of Satellite 1 cast by the light emitted by Satellite 4, assuming the fourth satellite to be self-luminous, but M. Flammarion's explanation is perhaps more simple, it being that since the atmosphere of Jupiter is very deep, the clouds would be at various depths, and at great distances from one another, so that sometimes the shadow of a satellite would fall either on the upper or on the lower clouds, or even on the disc itself. It is true that the distance between these shadows would be very small as seen from the earth, and in the actual observation here mentioned the distance between the shadows is comparatively large. Among other communications in the same journal we may mention M. Cornu's address on the discovery of minor planets by photography, M. Flammarion on the spring of 1893, some notes on the late total solar eclipse, and a brief reference to a proposed new astronomical station on Mount Mounier, at an altitude of 2800 metres.

GEOGRAPHICAL NOTES.

MR. F. G. JACKSON, whose proposed attempt on the North Pole by Franz Josef Land has been announced, has altered his plans. He now proposes to spend next winter in Nova Zembla, in order to familiarise himself with the conditions of Arctic life, and to test his sledges and other appliances for travelling over the ice. His more serious journey in Franz Josef Land has been postponed for a year, and will have a greatly increased chance of success.

VITA HASSAN, well known as Emin Pasha's apothecary in the Equatorial province, died recently. He had published a book on affairs in the Sudan, which throws some new light on the history of the Egyptian provinces before Stanley's expedition reached the Albert Nyanza.

A LADY traveller, Miss Taylor, of the China Inland Mission, has made a somewhat remarkable journey in Eastern Tibet, details of which will be looked for with much interest. Miss Taylor, who travelled alone, is expected soon to arrive in this country.

A GEOGRAPHICAL Club has recently been established in Philadelphia, which practically constitutes a new geographical society. It has published the first number of a bulletin containing a paper by Mr. E. S. Balch on mountain exploration, in which he endeavours to redeem mountaineering from the charge of being only a dangerous pastime.

THE coral reefs of Dar-es-Salaam, on the east coast of Africa, have been carefully studied by Dr. Ortmann, whose observations extend considerably our knowledge of fringing reefs.

THE ROYAL SOCIETY SOIRÉE.

THE President of the Royal Society received a brilliant company at the Society's rooms on the occasion of the annual ladies' *soirée* on June 7. Many of the exhibits were shown at the *conversazione* of May 10, and were noted in NATURE of May 18. Other exhibits are described in the following account:—

Mr. C. J. Woodward exhibited a bar over a resonance chamber illustrating sound interference. When a ventral segment is over the box a loud deep tone is heard. When the bar is placed so that a node is near the centre of the opening to the box no sound is heard, owing to opposite movements of the bar on either side of the node.

The Karakoram Mountain Survey Expedition exhibited Water-colour Drawings of the scenery of the Karakoram Mountains, Kashmir, India, by Mr. A. D. McCormick. These drawings were made at altitudes of from 15,000 to 20,000 feet, during the Expedition in 1892.

Prof. Osborne Reynolds, F.R.S., exhibited an illustration of vortex motion showing motion analogous to vortex rings in fluids.

Prof. Thorpe, F.R.S., exhibited autotype enlargements from photographs taken by himself, illustrative of the recent African Eclipse Expedition. The enlargements portrayed—(1) the eclipse party; (2) the observing party at Fundium, Senegal—taken immediately after the eclipse; (3) the duplex coronagraph; (4) the prismatic camera; (5) the integrating photometer; (6) the equatorial photometer.

Capt. McEvoy exhibited the hydrophone. This, in connection with a new instrument named a kinesiscope, is intended to be used at night, or in foggy weather; it has for its object the prevention of surprise attacks from torpedo-boats, or other hostile vessels, approaching anchorages, or mine-fields. It will give warning of their movements when they are several miles distant by ringing bells, flashing lights, &c. These signals in every case are verified by telephones in the circuit. The apparatus, which is electrical, may also be employed to warn vessels off dangerous points of the coast.

Dr. John Gorham exhibited a reflecting kaleidoscope, which is a new instrument adapted to produce not merely symmetric patterns of beauty, but to exemplify many of the theories in optics connected with the reflections of light. To do this changes in its construction are required to adapt it to its novel uses. The two mirrors, for instance, must be thrown open to admit the light upon them and the objects. The objects themselves must have a definite shape to cause them to reflect oblique rays of light only, while the light again must fall upon them from above, instead of being transmitted through them from below. These objects consist of strips of card bent backwards and forwards into hollows and elevations, upon which the light falls obliquely. It is then received upon the mirrors and reflected from them to the eye. Experiments were made to show:—(1) Gray tones from oblique white surfaces; (2) tints and shades of colour from oblique coloured surfaces; (3) depth, intensity, and brilliancy by repeated reflections; (4) the choice lustre, &c.

Mr. Edwin Edser exhibited an apparatus to illustrate Prof. Michelson's method of producing interference bands. Light is allowed to fall on a mirror thinly silvered, so that about half of the light is reflected and half transmitted. The two rays pursue paths which are mutually perpendicular, are reflected back by two ordinary mirrors, and on meeting interfere. The interference bands can be projected on a screen, and this fact together with the simplicity of the arrangements will make the method very useful for lecture illustration.

Mr. W. A. Shenstone and Mr. M. Priest exhibited an apparatus used for studying the action of the electric discharge on oxygen. A known volume of oxygen at known temperature and pressure is exposed to the "glow" discharge at known difference of potential. The change of pressure is read by a mercury manometer, and from this the proportion of ozone is calculated. The use of the mercury manometer, hitherto impossible, makes this method very accurate, and by means of it our knowledge of the influence of various conditions (such as difference of potential, rapidity of discharge) has been considerably extended. It is found that under equal conditions a coil is more effective than a "Wimshurst" or "Voss" machine. The using of mercury in the manometer is made possible by protecting it from the ozone by placing a rod of silver in the tube connecting the ozone generator and the manometer.

Mr. Percy E. Newberry was in charge of an exhibit by the Egypt Exploration Fund (Archæological Survey). The exhibit included water-colour drawings executed by the artists of the survey—Mr. Percy Buckman, Mr. John E. Newberry, and Mr. Howard Carter—during the past season, 1892–3. (1) Sketches of various sites visited by the officers of the survey, including views of Tell el Amarna, Sheikh Said and Dêr el Gebrawi. (2) Specimens of facsimile drawings of wall paintings from ancient tombs in the provinces of Minieh and Assiut (VI. and XII. dynasties, B.C. 3800 and B.C. 2500).

Lord Kelvin, Pres. R.S., exhibited illustrations of the molecular tactics of a crystal. (1) Bravais homogeneous assemblage of 512 single points. (2) Two homogeneous equilateral assemblages of points, red and green, with stretched springs between each point of the green assemblage and its nearest neighbour, and four struts between each of the reds and its nearest neighbour of the green assemblage; showing how any degree of resistance to compression with given rigidity can be provided for by Boscovich's theory. (3) Three-dimensional netting, analogous to the ordinary hexagonal netting of two dimensions. The stretched cords of this model are exactly in the positions of the struts of model No. 2. (4) Twelve nearest and eight next-nearest neighbours of an ideal particle at the centre of a cube, placed to show the cubic arrangement of an equilateral assemblage. (5) Cubic cluster of fourteen balls, being the least number which can show cubic form in an equilateral assemblage. (6) Probable molecular structure of Iceland spar. (7) Illustrating the molecular movement in the twinning of Iceland spar by knife according to Baumhauer. (8) Illustrating Baumhauer's artificial twinning of Iceland spar by knife. (9) Tetrahedron with adjustable edges (six independent variables). (10) Two geometrical models of:—(*a*) A dextro-chiral crystal. (*b*) A levo-chiral crystal. (11) Special tetrahedron, with perpendiculars from corners to faces, meeting in one point; to illustrate engineering of Boscovich's theory for an incompressible elastic crystal with 12 arbitrarily given rigidity moduluses.

Dr. G. H. Fowler exhibited specimens of oyster shells. The specimens illustrate:—(1) The rate of growth of the oyster. (2) Natural varieties of the shells. (3) Modifications of a variety bred under new conditions.

Prof. T. McKenny Hughes, F.R.S., exhibited abnormal and normal forms of oyster shells. The collection included oyster shells, showing the great variety of abnormal forms produced by accidental change in the position of the shells during growth, and also a selection of oyster shells, showing that among recent shells of *O. edulis* most of the forms occur which are considered of specific value in fossils.

The Joint Eclipse Committee exhibited the following photographs taken during the recent Eclipse Expeditions to West Africa and Brazil. (1) Photographs of the corona, taken in West Africa. (2) Photographs of the spectra of the corona and prominences, taken in West Africa. (3) Photographs of the corona, taken in Brazil. (4) Photographs of the spectra of the corona, and prominences, taken with the objective prism in Brazil. (5) Photographs of the stations.

Mr. W. H. Preece, F.R.S., exhibited submarine borers and specimens of submarine cables damaged by them. The *Xylophaga* and *Limnoria terebrans* have proved serious and expensive depredators in tropical seas, but while twenty years ago limnoria was practically unknown in our English waters, it has now gradually spread all around our coasts, and cables have to be served with brass tape to be protected from its attacks. Some stones pierced by *Saxicava rugosa* were also shown. They came from the Plymouth Breakwater. Several specimens of damaged cables from different parts of the world were exhibited.

The Zoological Society of London exhibited (1) a series of living Canadian walking-stick insects (*Diapheromera femorata*), hatched from eggs laid in the Society's insect-house in 1892. The "Walking-sticks" are orthopterous insects of the family Phasmidæ, so-called from their resemblance to sticks. They are strictly herbivorous, and closely imitate the plants upon which they feed, changing colour as the foliage turns in autumn. In North America the present species is said to do great injury to the oaks. These specimens are fed on hazel-leaves. (2) Living specimens of the Hornet Clearwing Moth of the Osier (*Sesia bembiciformis*), reared from pupæ in the Society's Insect-house. This moth affords one of the best known examples of "*mimicry*." Although belonging to quite a different order of insects, it resembles a hornet so closely as to deceive a casual observer, especially when it is on the wing.

Col. Swinhoe exhibited some species of butterflies, illustrating protective mimicry. Mimetic forms of the nymphalid genus Hypolimnas in India, Malayana and Africa, showing the various phases of development of mimicry in two widespread species of the same genus; also mimetic resemblances to different protected species in the females of *Euripus halitherses*, &c.

Prof. H. G. Seeley, F.R.S., exhibited fossil skulls from the Karoo Rocks of Cape Colony. These specimens were brought from Cape Colony by the exhibitor in 1889. They include examples of the chief types of fossil reptiles included in the Anomodont and Theriodont groups, preferable to the genera Dicynodon and Tapinocephalus.

Mr. Edward Whymper exhibited the Corry "protected" aneroid, a new form of aneroid, specially designed for use in mountain-travel, or for aeronauts. This form of mountain aneroid is designed to avoid the inaccuracies which result from continued exposure to low atmospheric pressure. It is enclosed in a perfectly air-tight outer case, and the internal atmosphere is kept at about a normal pressure at all times, except when an observation is to be taken, and then the cock is opened, and communication with the external atmosphere is established. After taking a reading, the pressure is restored to the normal by means of a small force pump. The conditions thus correspond to those which originally obtained, when the aneroid was graduated under the air-pump receiver.

Mr. J. W. Swan exhibited specimens of electrolytic copper, deposited bright. A series of electrolytic copper deposits, showing the great change produced in the character of the deposited metal by the addition of a minute quantity of colloid matter to an acid solution of sulphate of copper. The deposits produced from the solution containing the colloid are not only bright instead of being dull, but they are also very much harder and more elastic than ordinary electrolytic copper.

Prof. Henrici, F.R.S., exhibited (1) A harmonic analyser, constructed by G. Coradi, Zürich, according to instructions by Prof. Henrici and Mr. Sharpe. The instrument gives, on going once over a curve, the first five terms of the expansion in Fourier's series, and on going twice more over the curve, it gives five additional terms. The constant term is not given. (2) A calculating machine by Prof. Sellinger, constructed by Ott, Munich. This instrument is constructed on altogether new principles. The "carrying" is done continuously without jerks. It works very rapidly and smoothly.

In addition, Prof. J. Norman Lockyer, F.R.S., gave a lecture on the localities and instruments used during the eclipse of April 16, 1893, in West Africa and Brazil, with photographs showing some of the results obtained.

Mr. W. M. Conway also used the electric lantern to show photographic lantern slides, illustrating the scenery of the Baltoro Glacier in the Karakoram Mountains, Kashmir, India. The photographs were taken during Mr. Conway's climbing and survey expedition in 1892. Some of them were taken from the summit of the Pioneer Peak (22,500 ft.); the remainder represent the great mountains K2, Gusherbrum, Masherbrum, the Golden Throne, and others, probably the highest group of mountains in the world.

At intervals throughout the evening Mr. W. Bayley Marshall exhibited the lantern-stereoscope (invented by Mr. John Anderton). The images of a pair of stereoscopic transparencies having been superposed on a 10-foot screen, the beams of light from the two lanterns were polarised in planes at right angles to each other. The picture was viewed through a pair of analysers, similar to a small opera glass, and a true stereoscopic effect was obtained.

THERMOMETER SOUNDINGS IN THE HIGH ATMOSPHERE.

THE project, which was suggested by Le Verrier in 1874, of sending small balloons into the upper atmosphere with registering apparatus has been executed recently by M. Hermite, in Paris, with remarkable success. No fewer than thirteen small balloons, constructed with paper and varnished with petroleum, were liberated during the last four months of 1892, and penetrated to an altitude of 9000 metres. A paper balloon of 60 cubic metres capacity was sent up on December 7, but exploded at a small distance from the earth. It was therefore resolved to build a balloon of 113 cubic metres capacity in gold-beaters' skin. The launching of this balloon took place on March 21 last, at Vaugirard, with the help of the Aerophytic Union of France, of which I have the honour to be the president. The balloon was filled with 113 cubic metres of coal-gas. Its weight with netting was about fourteen kilograms. It carried in a small basket a Richard registering apparatus for temperature and pressure, and about seven hundred postal-cards, to be liberated by the combustion of a cotton string specially prepared for the purpose. This part of the operation utterly failed. Although the fire was put to both extremities of the string, it was extinguished before all the cards had been sent down, and out of four hundred which were precipitated, no more than five or six were recovered. Thus, the hope of determining the path by dropping such objects from an immense height had proved futile. But the recovery of the balloon at 190 km. from Paris was very easy, and the registering apparatus was returned to its owner in excellent working order. The diagram, which had been traced on the revolving cylinder, has been submitted to a close inspection, of which the results have been published in the *Comptes Rendus* and *l'Aerophile*, a new periodical devoted to the study of aeronautics.

The registering of the pressure had been continued down to 95 mm. of mercury, which answers to something less than 17,000 metres, if Laplace's formula is valid even for this altitude. A temperature had been registered of $-51°$ C. $= 60°$ below zero Fahr. at a level of about 14,000 metres, according to the same formula. The temperature on the ground being $+17°$, a diminution of $67°$ C. was thus found, which is about a degree for each 210 metres. The atmosphere being supposed to extend up to 180,000 metres, it is easy to see that these numbers are an indication that the cold of the upper regions is much greater than supposed according to Fourier's theory, which asserts that the greatest degree of cold observed at the surface of the earth, viz. 58° registered by Black in Northern America is about equal to the temperature of celestial space.

This remarkable observation is not however to remain long isolated, as Commander Renard, of Meudon, has built a set of registering apparatus, which were exhibited recently at the anniversary meeting of the *Société de Physique*, and will be sent up very shortly with a 113 c.m. balloon inflated with pure hydrogen. So a new departure may be said to have been taken for the scientific exploration of the air at an altitude where no human being can penetrate. The series of prizes proposed by M. Hodgkins for 1893 and 1894, and the creation of the Hodgkins medal by the Smithsonian Institution, certainly add new interest to these experiments.

M. Janssen intends to establish an apparatus for making pure hydrogen in the Meudon Observatory in order to help M. Hermite to send his sounding balloons to a higher level if possible. He will, moreover, try to measure by direct observation the altitude of the balloons sent, as long as they remain visible from his Observatory.

This last scheme was adopted by Le Verrier, who says in the *Bulletin de l'Association Scientifique de France* for October 1874: "La hauteur du ballon est toujours déduite de la mesure du baromètre et du thermomètre, au moyen d'hypothèses sur la repartition de la pression atmosphérique. Il s'agit d'écarter ces causes d'incertitude, et de mesurer directement par des opérations trigonométriques la hauteur même du ballon; ce qui permettra de vérifier les lois admises ou de les modifier. Les opérations trigonométriques à terre seront faites par les astronoms de l'observatoire sur le charge de cette partie des dépenses. La direction de l'aerostat fourni par l'observatoire est confiée à M. W. de Fonvielle." The protracted illness of the illustrious astronomer and his subsequent death, prevented the series of ascents from being tried as contemplated.

The experiments already tried by M. Hermite, namely, on March 3, prove that the balloon will remain long visible from an Observatory, if the ascent is executed on a clear and calm day with a considerable ascending force, which gold-beater's skin can support without being torn by the friction.

The ascent of March 21, when ordinary gas was employed, took place with such velocity that the balloon was seen always nearing the zenith, independently of the diverging direction of the air, the mean recorded velocity having been eight metres per second from the time of starting to the time of maximum, which was reached in three-quarters of an hour, according to the automatic barometer.

The inflating pipe (*appendice*) which the balloon carried with it, was 30 cm. diameter and 90 cm. long, and air took the place vacated by the retreating gas, when the balloon descended. Consequently it was found quite full when discovered, just the same as when the balloon was liberated. The only differenec was that the gas had been expelled and replaced by air.

Since the volume of the balloon remained quite constant during the whole of the operation, it would have been quite easy to determine the absolute distance from the observatory by measuring the apparent diameter with a micrometer. By taking simultaneously a reading of zenith distance and azimuth, it would have been quite easy, by a series of observations conducted from a single station, to ascertain the altitude of the balloon and every circumstance of its motion.

The principal object of M. Janssen will be to determine the absolute minimum of temperature at the maximum altitude, which can be done more or less precisely, and the direction or velocity of the winds blowing at different altitudes. Then the indications of the registering instruments can be submitted to the rational control which is necessary before coming to any definite conclusion.

It is interesting to notice that these preliminary results are in conformity with the Joule and Clausius theory, which asserts that celestial space is at the temperature of $-273°$ C., or even with the opinion that there is no limit to the refrigeration, as asserted by other natural philosophers.

Another question is raised by these experiments, when coupled with Dewar's and Cailletet's discoveries relating to the liquefaction or solidification of the elements of the air. If the temperature descends to such a degree it is necessary to admit that the air loses its gaseous condition and becomes changed into a series of minute crystals or drops, which follow the earth in its motion through space, and are constantly vapourised when falling in regions where the temperature is somewhat above their point of liquefaction or evaporation.

Such are some of the questions raised by this new exploration of elevated regions, rendered very easy by the unexpected facility with which balloons and instruments in working order are recovered. This has been rendered possible in France by the interest taken in the matter by public schoolmasters, who have been notified of the experiments by the newspapers, and have found special instructions printed on a paper pasted to the basket. It is certain that similar results may be obtained in every civilised country in the world, and we trust this new method will develop and improve so that unquestionable facts will be discovered with regard to the mysterious cosmical frontiers of our globe.

W. DE FONVIELLE.

DISINFECTANTS AND MICRO-ORGANISMS.

SOME important results have recently been obained by Heider, who has been experimenting with disinfectants at higher temperatures and testing the effect produced upon their bactericidal properties. The author's first contributions in this direction were published in 1891. In Heider's original communication, "Ueber die Wirksamkeit von Desinfektionsmitteln bei höherer Temperatur" (*Centralblatt für Backteriologie*, vol. ix. 1891, p. 221), temperatures of 55° and 75° C. were employed, and the spores of anthrax were selected for investigation. Although these spores, it was ascertained, survived an immersion during 36 days in a 5 per cent. solution of carbolic acid kept at the ordinary temperature of the room, they were destroyed in from one to two hours in a similar solution at 55° C. Weaker solutions of this acid (1 per cent. and 3 per cent.), even when maintained at the higher temperature for seven and eight hours, produced no effect upon the anthrax spores. On the temperature being raised to 75° C., however, three minutes' exposure to a 5 per cent. solution of carbolic acid, fifteen minutes to a 3 per cent. solution, from two to two and a half hours to a 1 per cent. solution sufficed to annihilate these spores. Other materials were also investigated at these high temperatures, and equally satisfactory results obtained. Heider has brought together all his researches on this interesting subject in an elaborate memoir, "Ueber die Wirksamkeit der Desinfectionsmittel bei erhöhter Temperatur," which has been published in the *Archiv. für Hygiene*, vol. xv. p. 341. It is pointed out how great an effect upon the powers of resistance possessed by micro organisms may be exercised by the nature of their surroundings, and that it may be taken that they are, as a rule, more refractory in their normal environment than when purposely introduced into various materials. This has been shown by Yersin, in respect to the tubercle bacillus, which succumbs more readily to certain temperatures when exposed in artificial cultures than in sputum. Heider also found that particular culture media had a remarkable effect in this respect upon bacteria, that, for example, those grown in sugar broth (3 per cent. cane sugar) proved far more capable of resisting exposure to a high temperature than those introduced into ordinary broth. In conclusion, it having been distinctly proved that the bactericidal action of the majority of disinfecting materials is markedly increased when they are employed at a higher temperature, the author recommends that in all those cases where the destruction of spores is required, instead of applying these materials in cold solutions, they should be employed hot, or even boiling. The advantages derived by so doing are not alone the greater security obtained and saving of time, but economy in the cost of material, inasmuch as effectual sterilisation may be accomplished by the use of less concentrated solutions.

THE NEW FLORA AND THE OLD IN AUSTRALIA.

A VERY interesting paper on the effect which settlement in Australia has produced upon indigenous vegetation, by Mr. A. G. Hamilton, appears in the new number (vol. xxvi.) of the "Journal and Proceedings of the Royal Society of New South Wales." Mr. Hamilton traces with great care the results which have sprung from the direct action of man. He then deals with the alteration of the flora by the introduction of a new fauna, and the modification of it by the destruction of the native fauna. Finally, he considers the introduction of a new flora, and the consequent modification of the indigenous flora through competition.

The following is the portion of the paper relating to the effects due to a new flora:—

The plants which have become naturalised in Australia naturally come under two headings, viz. those purposely introduced for use, ornament or sentiment, and those which accidentally found their way here.

Of those introduced for use or for ornamental purposes, a large number do not spread to any extent: they are children of civilisation and show no tendency to become feral. Many hardy annual garden flowers come up self-sown in gardens year after year and yet never gain a footing outside. Others again, which have the power of spreading rapidly, are never able to do so, as they are succulent feed, and cattle take care that they never multiply. Such are oats and other grains. Wheat never seems to spread at all away from the fields in which it is cultivated. But still there are numbers of useful plants which are able to hold their own and more. Among these may be mentioned the lemon, peach, Cape gooseberry, tomato, and passion fruit, all of which are wild in many parts of the Illawarra district, and continue to bear fruit. Another species of passion flower (*Passiflora alba?*) is common there and is even more plentiful than the edible species. It is bitter and nauseous, but has spread over large tracts of bush country, converting them into tangle of the densest description. The common bramble or blackberry has been introduced for the sake of its fruit, and is now beginning to be a troublesome tenant of unoccupied lands in the cooler parts of the Colony. It reaches a development far exceeding that attained in its native land.

Sweet-briar and Scotch thistles are said to have been introduced for the sake of the associations clustered round the plants in the mother country. The latter plant is reported to have been introduced into Tasmania by a patriotic Scotchman desirous of having his national plant growing near his new home. He appears by all accounts to have succeeded only too well.

But with regard to most introduced plants, there is much difficulty in discovering the method of introduction. The plants which habitually flourish in European cornfields are certainly easily accounted for—they came in the seeds imported to the Colonies. Such are corn marigold, corn spurrey, and many of the Caryophylleæ, the cornfield poppy and numerous others which will occur to every one. Then again, many noxious weeds growing among grain, were introduced to Australia in straw in packing cases. Such are the Centaureas and others. As an example of this I may note that *Bupleurum rotundifolium* first appeared in the Mudgee District in a yard where a box from England was unpacked.

But with many plants introduced, we can only reason by analogy as to the manner of their introduction. In an article on the weeds of Europe in the *Cornhill Magazine*, an anonymous writer states that a common English weed was introduced into an Antarctic island by the use of a spade which had some mould attached to the blade, and the plant has now spread all over the island. Darwin gives instances of seeds being found in balls of clay attached to the feet of birds, and even to the elytra of beetles. Still, the method of introduction of many foreign weeds must in the nature of things always remain more or less of a mystery. Many aliens have arrived in the colony attached to the wool of sheep or the hair of other animals as in the case of the Bathurst Burr—a species of vegetable stowaway.

As to the methods of spreading, they are various. Cultivation of the soil brings the weeds in its wake, and they manage to spread somehow. Some have specially constructed seeds to float through the air—any one who has seen thistle-infested country on a windy day will have a good idea how thistles spread. The Composites are especially rich in plants adopting this contrivance. Others stick to the wool and hair of animals by hooks, barbed hairs, or sticky glands. Others again have seeds so minute that a high wind will carry them, although they are not furnished with special apparatus for the purpose.

Railways and roads are active helpers in the dissemination of aliens, especially the former. The land being fenced in is protected from the depredations of stock, and thus protected the weeds flourish and spread rapidly. In 1887 I remember noticing on the Mudgee Railway near Lue that there were miles of the embankments one tangled mass of *Meliotus parviflorus*. And in the neighbourhood of Bowenfels the railway line enclosures are thickly covered with a species of *Hypochæris*: it is pretty plentiful outside but inside the land is a golden sheet of the yellow flowers. Rivers also act in the same way, and especially carry weeds when in flood and deposit them on the flooded lands. I first noticed *Ranunculus muricatus* and Fool's parsley on the river banks at Mudgee. The following year they had reached Cullenbone, and the next year had got as far as Guntawang, a distance of seventeen miles by road but at least twenty-five or thirty by the river. A curious instance of the spread of a plant from one locality to another was afforded me in 1886 and 1887. During a journey from Guntawang to Wellington, a distance of forty-two miles, I noticed at Wellington, on the river banks, great quantities of *Cassia sophora*. At that time none of the plant was found in the Mudgee District, but in the same year a mail coach commenced running from Wellington to Gulgong passing through Guntawang. The following year, two plants of the *Cassia* appeared at Guntawang, and soon after it began to be common in the district. The Rev. Dr. Woolls, at a meeting of the Linnean Society of N.S. Wales, in September 1890 exhibited plants of *Calotis scapigera* and *C. hispidula* from Concord and Burwood. These are strictly denizens of the interior and were probably brought down by sheep travelling to the sale yards. Indeed I feel pretty sure that an examination in the neighbourhood of the Homebush sale yards would show that many western plants are brought down by the sheep, etc. In collecting introduced plants, I have always been most successful by roadsides, riverbanks, and railway enclosures, and there can be no doubt but that they are the principal lines of travel for these plants.

The plants which have edible fruits containing indigestible seeds are for the most part dispersed by birds and mammals which eat the fruit and void the seeds in new localities. In this way passion fruit, blackberries, *Phytolacca*, tomatoes, solanums, Cape gooseberries, and many others are distributed.

It is a significant fact that horehound—*Marrubrium*—is always plentiful in the vicinity of a sheep station. Two other plants commonly found in the same situation are the introduced nettles, *Urtica urens* and *U. dioica*, whether from the plants being eaten by the sheep and the undigested seeds voided, or because that in sheep-manured land they find a congenial soil, I am unable to say.

Australian plants from their long isolation, and their having little competition of a severe kind, settled down into a state of balance or rather of slight oscillation, governed by a few causes, which themselves varied but little. In the older continents, however, from the intercommunication of the various nations, and from the fact that men continually add to their stock of cultivated plants, there is severe competition; the struggle for existence goes on continually and aided by natural selection and domestication some plants gain an advantage.

Among other, useful habits acquired by plants under competition is a certain plasticity of constitution which enables them to bear changes to different climates with equanimity. On this account the old world weeds when brought to Australia are able to beat the native plants. They are mostly plain dwellers, and as such accustomed to the heat of the sun in the open, and the bitter blasts of the winter, better than forest plants. When forests are cleared and brought under cultivation, the weeds soon beat the former occupants out of the field. Again many old world weeds are plants of wide range, and on this account have an advantage over those of more restricted habitat.

"Widely varying species abounding in individuals which have already triumphed over many competitors in their own widely extended homes, will have the best chance of seizing on new places when they spread into new countries. In their new homes they will be exposed to new conditions, and will frequently undergo further modification and improvement; and thus they will become still further victorious and produce groups of modified descendants." ("Origin of Species," 6th ed. p. 319.) As before remarked their success in competition implies a plasticity of organism which is an advantage to them also; on this subject Darwin says, "If a number of species, after having long competed with each other in their old home, were to migrate in a body into a new and afterwards isolated country, they would be little liable to modification or variation; for neither migration nor isolation in themselves effect anything." (*Op. cit.*, p. 319.) The isolated productions of Australia on the other hand, have had uniform conditions and comparatively small range and so they cannot make way against those that have had such competition and range.

"In the same manner at the present day, we see that very many European productions cover the ground in La Plata, New Zealand and to a lesser extent in Australia and have beaten the natives, whereas extremely few southern forms have come to be naturalised in any part of the northern hemisphere, though hides, wool and other objects likely to carry seeds have been largely imported into Europe during the last two or three centuries from La Plata, and during the last forty or fifty years from Australia." (*Op. cit.*, p. 340.) Wallace says, "There is good reason to believe that the most effective agent in the extinction of species is the pressure of other species, whether as enemies or merely as competitors." ("Island Life," p. 63)

It is well known that few Australian plants have found a footing in Europe notwithstanding the many facilities which commerce offers for their introduction, and the few American weeds which have found their way to Europe do well only in the Mediterranean region. Even in New Zealand but a few Australian plants have become naturalised, as is shown by Mr. T. F. Cheeseman's paper on the naturalised plants of Auckland (read before the Auckland Institute, November 1892).

In America, the majority of introduced weeds are European, though at first they completely beat the natives, it is noteworthy that now the natives are holding their own, and even beating the strangers, thus showing that competition has gone on long enough for some advantage to be gained by the natives. It is remarkable too that the plants of Eastern America immigrated westward with man, and conquered the western plants at first; but from a consideration of the facts the great American botanist Prof. Asa Gray was led to prophesy a return wave of western plants, and that is now actually coming.

The theory that insulated floras are less able to resist the influx of foreign plants is supported by the fact that only in the Neilgherrie Mountains in India have Australian plants been able to compete with others to any extent. It is, I believe, considered that that part of India long existed as an insular region. Therefore we see that the Australian flora, which though isolated, had a large range, is able to get an advantage over the Neilgherrie flora which was for so long developed in a small centrum.

One cause of the power of spreading of what are commonly called weeds is that they are usually plants with inconspicuous flowers, and as such are generally self-fertilised and so can get along without specialised insects to fertilise them. It is manifest that in a new country where the local insect fauna is being destroyed to some extent, the plants which have not to depend on insects for fertilisation will be the more likely to win. And even cross-fertilised plants seem to manage sometimes to find insects to perform that office for them. Moseley points out an instance in the following passage:—"The orange, lemon, and lime, which grow wild all over Tahiti do not appear to deteriorate at all in quality or quantity of fruit, although in the ferine condition. The fruit almost appears finer for running wild. . . . . Some native insect must have adapted itself completely to the blossoms of the orange tribe as fertiliser, so abundant is the fruit." ("Notes of a Naturalist on the *Challenger*," p. 524.) The same is the case in Australia, for although the orange does not seem to grow wild to any extent, lemons have made themselves at home in the Illawarra district. The flowers of the lemon and the native plant *Synoum glandulosum* are much alike in structure, and it may be that the same insect or insects fertilise them. These plants would be on equal terms in this respect, but the lemon from its wide cultivation has gained a power of bearing diverse conditions, which gives it a better footing. I may remark that *Synoum* is a common plant in Illawarra.

Among wind-fertilised plants are the grasses. The introduced species so far are not beating the natives. They are equal as far as regards fertilisation, but most introduced species are from cool temperate regions, and so the Australian species being warm temperate, are able to hold their own. The dying out of some Australian grasses is attributable to over stocking and close feeding and not to competition.

In considering the introduction of weeds in Australia there is a great difficulty viz. that it is hard in some cases to say whether c rtain plants are indigenous or alien. It is considered a safe rule to take all plants common in the colony in Robert Brown's time as truly indigenous, but as Brown only collected in the neighbourhood of Port Jackson, that course leaves some difficulty still. On this subject Baron von Mueller says in the preface to his "Census of Australian Plants" (1st Edit. 1882)—"The lines of demarcation between truly indigenous and recently immigrated can no longer in all cases be drawn with precision; but whereas *Alchemilla vulgaris*, and *Veronica serpillifolia* were found along with several European *Carices* in untrodden parts of the Australian Alps during the author's earliest explorations, *Alchemilla arvensis* and *Veronica peregrina* were at first only noticed near settlements. The occurrence of *Arabis glabra*, *Geum umbrosum*, *Agrimonia eupatoria*, *Eupatorium cannabinum*, *Carpesium cernuum*, and some others will readily be disputed as indigenous and some questions concerning the nativity of various of our plants will probably remain for ever involved in doubts." As will be seen from this, the origin of some plants will and must remain more or less a matter of personal opinion. And on referring to lists of plants of the various colonies it will be found that their authors differ in their placing of these doubtful plants. If we critically examine the Census of New South Wales plants by Mr. C. Moore, of Queensland plants by Mr. F. M. Bailey, of Victorian by Baron Von Mueller, and of New South Wales by Dr. Woolls, we shall find abundant evidence of diversity of views in this respect. But very many weeds present no difficulty at all, although the record of their plentiful occurrence in very early days may well surprise us. The Rev. J. E. Tenison-Woods ("Proc. Linn. Soc. of N.S. Wales," vol. iv., p. 133) remarks that Leichhardt found *Verbena bonariensis* so plentiful in the neighbourhood of Darling Downs, then only five or six years settled, that he named the place Vervain Plains.

The injury done by introduced weeds will be almost entirely by competition, but it is possible that in time, the Australian plants may begin to hold their own and even to some extent drive out the others. This will be more especially the case with the group of plants which are found on the barren and sandy tracts wherever the Hawkesbury Sandstone formation occurs. In such land few aliens get a footing. On the sandstone about Sydney as a rule, and in the Blue Mountains where the same soil occurs, the foreign weeds have no chance. But wherever the soil is fairly good, or where it has been broken up, there they triumph and exclude the indigenes.

To some, extent however, the weeds will work their own destruction. They increase so rapidly that competition is most severe, not between them and the natives, but between individuals of the same alien species, or between distinct alien species. *Sisymbrium officinale* was once a pest near Mudgee, the fallow and unoccupied land being covered with a thick mass of it; but after the lapse of a few years it became quite rare, and *Erigeron canadense* took its place. I think that in some cases the fact of a heavy crop of weeds occurring in a locality one or more years is a reason for expecting its scarcity in the following years. The soil becomes exhausted of the particular constituents demanded by the plants, and they fail in consequence. I had often read doleful prophecies of the damage that might be expected when the Cape weed (*Cryptostemma calendulaceum*) became common. When I first saw it appear in Illawarra, I was therefore prepared to see much land infested by it in a short time. It spread to a great extent in certain spots for a couple of years and then almost disappeared. In my garden half-a-dozen vigorous plants came up, and as I left them for the purpose of observation, they flowered and seeded plentifully. I fully expected a large crop the following year, but to my surprise not a single plant was to be found, nor has there been on

Mr. T. Kirk, in a paper on the naturalised plants of Port Nicholson, N.Z., says:—"At length a turning point is reached, the invaders lose a portion of their vigour, and become less encroaching, while the indigenous plants find the struggle less severe and gradually recover a portion of their lost ground, the result being the gradual amalgamation of those kinds best adapted to hold their own in the struggle for existence with the introduced forms, and the restriction of those less favourably adapted to habitats which afford them special advantages." (Trans. N. Z. Inst., vol. x., p. 363) And Mr. T. F. Cheeseman, from whose paper on the "Naturalised plants of the Auckland District" I have quoted the above, coincides with this opinion to some extent and says, "Speaking generally I am inclined to believe that the struggle between the naturalised and the native floras will result in a limitation of the range of the native species rather than in their actual extermination. We must be prepared to see many plants once common become comparatively rare, and possibly a limited number—I should not estimate it at more than a score or two—may altogether disappear, to be only known to us in the future by the dried specimens in our museums."[1] If this is likely to be the case in a territory so limited as New Zealand how much more is it probable in Australia with the vast extent of area, diversified surface and various climates from tropical to cold temperate.

[1] Paper read before the Auckland Institute, November 1892.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 9.—"On the Geometrical Construction of the Oxygen Absorption Lines Great A, Great B, and α of the Solar Spectrum." By George Higgs. Communicated by R. T. Glazebrook, F.R.S.

In the early part of August, 1890, the photographic work of the normal solar spectrum which I had undertaken had been carried as far as great A, or the limit of visibility in the red, and to λ 8350, or beyond z, in the invisible regions.

During the two previous months of continuously dull weather, while classifying and comparing results, I was interested, on making a close examination of the head portion of the A line, to find, the rhythmical grouping, the harmonic order of sequence, and other characteristics of the B line repeated here in every detail.

These two bands, together with alpha, are composed of a number of doublets or pairs, which approach each other on the more refrangible side with uninterrupted regularity, finally crossing, and at the limiting edges of all three bands the three last pairs overlap each other.

The differences of wave-length between the components of pairs increase in the same order.

These and other properties, which will be referred to, are still more obvious in the trains or flutings.

From its holding an intermediate rank in each of its distinguishing characters I was induced to adopt B as a typical group in a geometrical representation, and to investigate the subject by means of rectangular co ordinates.

FIG. 1.

Before a complete analysis could be made out, a micrometer had to be completed. This consisted of a platform, serving as a plate holder, which was made to travel on runners between parallel ways by means of a screw of such a pitch as to move the negative from one division of the scale to the next, for one revolution of the divided plate on the screw head, this latter being divided into 100 parts.

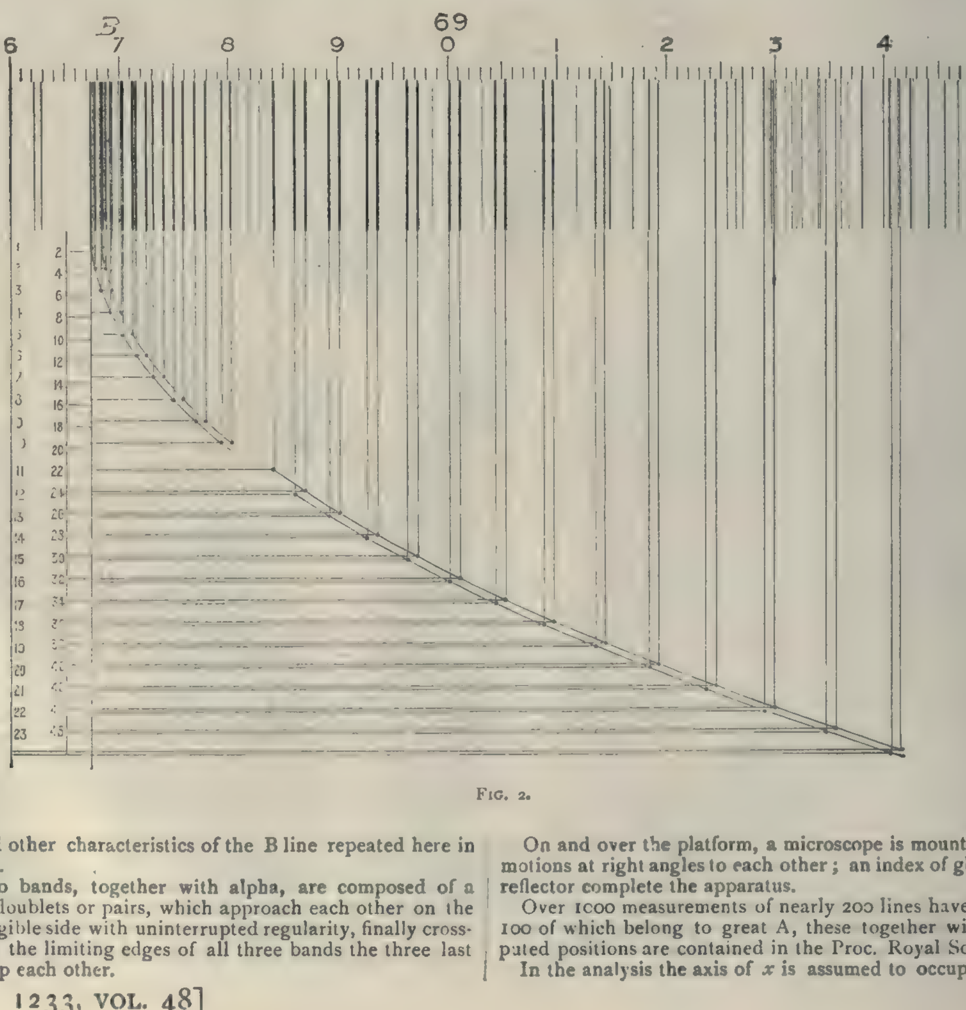

FIG. 2.

On and over the platform, a microscope is mounted with slide motions at right angles to each other; an index of glass fibre and reflector complete the apparatus.

Over 1000 measurements of nearly 200 lines have been made, 100 of which belong to great A, these together with the computed positions are contained in the Proc. Royal Soc.

In the analysis the axis of x is assumed to occupy a position coincident with, or parallel to, the scale of $1/10^{10}$ m. units, and the positions of the various lines are set off on this scale (see Fig. 2) for the group, which is divided into four series. Ordinates are then drawn in the position occupied by each line. The axis of y is divided into a number of equal parts, 1, 2, 3, n. Lines parallel to the axis of x, drawn from each of these divisions, intersect the respective ordinates. The continuous curve passing through the points of intersection is found to possess all the properties of a parabola.

Three points at least are selected to determine the position of the vertex and value of latus rectum. The distance from the origin along y is also found for an ordinate to the first line of a series.

Now, from the equation to the parabola $y^2=px$, the formula $\lambda = V + \frac{(n+c)^2}{p}$ is derived, where V = the wave-length in $1/10^{10}$ m. units of a point in the spectrum coinciding with the vertex of the curve; p, the latus rectum; n. any number of units, reckoning from the origin; c, a constant.

In practice a representation more suitable for lantern projection being desirable, two units are taken on y for each line of the series; the equation then becomes $\lambda = V + \frac{(2n+c)^2}{L}$, where $L = 4p$, and c has twice its former value.

April 20.—"Magnetic Viscosity." By J. Hopkinson, D.Sc., F.R.S., E. Wilson, and F. Lydall.

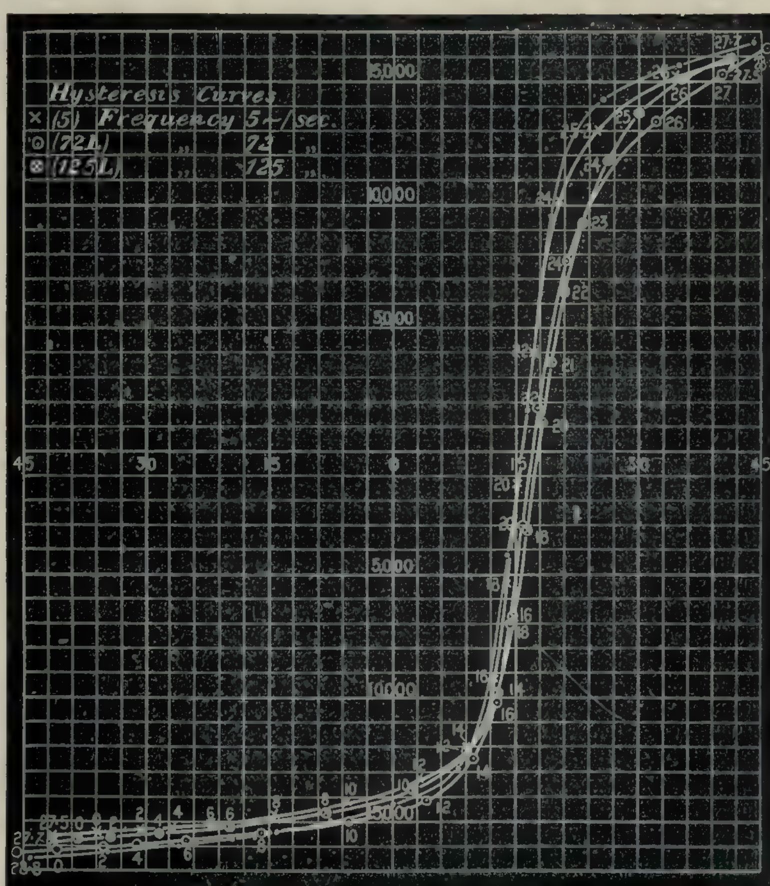
In some experiments carried out by Dr. J. Hopkinson and B. Hopkinson, an account of which appeared in the *Electrician* of September 9, 1892, it was found that when hysteresis curves were obtained for rings of soft iron and hard steel wire by means of alternate currents, and compared with curves taken with the ballistic galvanometer, in the cases where the induction was considerable, there was a marked difference which might be due to magnetic viscosity or to the ballistic galvanometer.

To settle this question the experiment was tried of completing the galvanometer circuit at known intervals of time after the magnetising force had been changed, and noting the deflection. The effect of the self-induction of the ring was approximately calculated, and found inadequate to account for the deflections obtained.

Next, the experiments previously alluded to were continued, and curves of hysteresis obtained with alternating currents of a frequency of 5, 72, and 125 v per second, the method of procedure being exactly the same. In all the curves thus obtained it was seen that the more rapid the change of magnetising force, the greater was the deviation from the curve taken with the ballistic galvanometer. The accompanying figure gives the hysteresis curves actually obtained, and show this point very clearly.

Similar experiments were carried out on hardened chromium steel, and the same effect was observed but was not so marked.

The following conclusions are drawn from the experiments:—(1) As Prof. Ewing has already observed, after sudden change of magnetising force the induction does not at once attain to its full value, but there is a slight increase going on for some seconds. (2) The small difference between the ballistic curve of magnetisation with complete cycles, and the curve determined with a considerable frequency which has already been observed is a true time effect, the difference being greater between a frequency of 72 v per second and 5 v per second, than between 5 v per second and the ballistic curve.



June 1.—"On the Metallurgy of Lead." By J. B. Hannay. Communicated by Sir G. G. Stokes, F.R.S.

In this paper the author deals with the result of seven years' researches on the metallurgy of lead.

It is shown that by repeated crystallisation any subsulphide of lead may be fractionated into metallic lead, and its monosulphide. The sp.gr. of pure monosulphide is found to be 7·766, and the methods of analysis are reviewed and corrected.

The reaction, $PbS + PbSO_4 = 2Pb + 2SO_2$, which was supposed to explain lead smelting, is shown to have no existence, as when lead sulphate and sulphide react upon each other, a volatile compound, PbS_2O_2 or $PbS.SO_2$, is formed which introduces complications, and being unknown to chemists was the cause of the errors in the accepted furnace reactions of lead.

This substance is formed whenever its constituents PbS, and SO_2, meet at high temperature, and is the cause of lead fume. Similar volatile compounds are formed by the gases CO_2, CO and H_2O. These bodies dissociate on cooling, but form colourless gases at a red heat.

All the furnace reactions of lead compounds are examined and corrected in the light of these discoveries, and the fact applied to explain the metallurgy of lead.

A new metallurgy is mapped out by which galena is treated in a Bessemer converter, and made into pig-lead, litharge, or sulphate of lead, in any proportions as may be desired, while all the silver is eliminated.

"Flame Spectra at High Temperatures. Part I. Oxyhydrogen Blowpipe Spectra." By W. N. Hartley, F.R.S.

The substances examined are supported in the oxyhydrogen flame on small plates of kyanite. This mineral contains ninety-six per cent. of aluminium silicate, and is practically infusible. The spectra were all photographed. The dispersion of the instrument being that of one quartz prism of 60°.

The spectra of a large majority of the metals and their compounds all terminate somewhere about the strongest series of water vapour lines in the ultraviolet. Typical non-metallic spectra are sulphur, selenium, and tellurium; the first yields a continuous spectrum with a series of beautiful fluted bands, the second a series of fine bands, occurring at closer intervals, and the third is characterised by bands still closer together and near the more refrangible termination of which four lines occurring in Hartley and Adeney's spark spectrum of tellurium are visible. Increase in atomic mass causes shorter periods of recurrence of bands. In line spectra it is the reverse; increase in atomic mass causes greater periods in the recurrence of lines. Charcoal and carbon monoxide yield chiefly continuous spectra; the latter, however, exhibits some carbon lines. The hydrocarbons yield the well-known spectrum of carbon bands with also those attributed to cyanogen. Of metallic elements, nickel, chromium, and cobalt yield purely line spectra; antimony, bismuth, silver, tin, lead, and gold beautiful banded spectra (spectra of the first order) accompanied by some few lines.

Iron and copper exhibit lines, and, less prominently, bands. Manganese has a beautiful series of bands and a group of three very closely adjacent lines. Aluminium gives a fine continuous spectrum with three lines, origin uncertain, zinc a continuous spectrum without lines, and cadmium a spectrum consisting of one single line only, λ 3260·2.

Of compounds, chromic trioxide yields a continuous spectrum with six lines belonging to the metal, copper oxide a fine band spectrum with two lines of the metal, magnesium sulphate gives a spectrum of magnesium oxide consisting of broad degraded bands composed of closely adjacent fine lines and one line belonging to the metal, λ 2852.

The sulphates of calcium, strontium, and barium give both bands of the oxides and lines of the elements. Phosphorus pentoxide yields a continuous spectrum with one peculiar line, seen also in the spectrum of arsenic.

The chlorides of the alkali metals give also lines of the elements with a more or less continuous spectrum, which, it is believed, is due to the metal in each case. Lithium chloride gives no continuous spectrum.

The Volatility of Metals.—One of the most interesting facts ascertained by this investigation is the volatility of all the metals examined, except platinum, and particularly the extraordinary volatility of manganese, and, to some extent, of the infusible metal iridium. Metal believed to be pure iridium is seen to have diminished after the flame has played upon it for about two hours.

Physical Society, May 26, Prof. A. W. Rücker, F.R.S., President, in the chair.—Mr. C. J. Woodward showed some experiments with a vibrating bar. On suspending the bar by two loops of cord, and placing it over a resonance box, the sound was greatly intensified. When placed crosswise, and partly over the box, a position could be found where no increase of sound resulted, whilst a little movement in either direction from this position caused a considerable increase.—The discussion on Dr. Lodge's paper, the foundation of dynamics, was then resumed. Communications on the subject from Mr. S. H. Burbury, Dr. G. Johnstone Stoney, and Prof. E. F. Herroun were read. Prof. Minchin said the first fundamental axiom of dynamics postulates the existence of *Force* as an entity distinct from *Matter*, *Space*, and *Time*, and this was the object of Newton's First Law. It also gave the criterion of the presence of force. To merely retain the law as defining *equal times* was to degrade it. As regards the supposed impossibility of defining uniform motion he said, similar difficulties occur in all sciences, even in geometry. Nevertheless a rational science of geometry existed. In dynamics we had notions of a right line and of uniform motion in it, although no criterion of either may exist. The fact that the science harmonises with ordinary experience constitutes its validity. In his opinion the extraordinary devices which had been suggested for defining directions fixed in space were unnecessary, and merely served to cover the subject with ridicule. He disagreed with Prof. Lodge in admitting the first law as a particular case of the second, for unless force was postulated (the function of the first law), the second became a mere definition, and not a law. Speaking of the third law he said the author had made a serious error in stating that it could be deduced from the first, for the centre of mass of a system might be at rest, without action and reaction necessarily being equal and opposite. The third law was not superfluous; neglecting it had led to great misconception and mystery about the Principle of Virtual Work, and D'Alembert's Principle, both of which are simple deductions from it. In opposition to Dr. Lodge, he defended the ordinary definition of Energy, and asserted that without the notions of *force* and *work*, the term *energy* loses all meaning. Speaking of transference and transformation of energy, he inquired if the proof given could be applied to the case of a body sliding down a rough rigid inclined plane, for here the stress (friction) does work on the body but not on the plane, and there was no transference. He regretted that the expression "potential energy" was used in different senses in the paper, sometimes meaning "static energy," and at others "the available portion of the kinetic energy of a body." Referring to the idea of all energy being ultimately kinetic, he asked if by accepting this the author meant to surrender the independent existence of force. If so, difficulties would arise; for example, in the kinetic theory of gases the expression for the pressure, $p = \frac{1}{3} \rho v^2$, was only arrived at by assuming the existence of force. The statement on the top of slip 9 about making a "moving body do work" was not necessarily true, as might be seen by considering the case of a sphere rolling down a rough inclined plane. Prof. O. Henrici thought axioms should be treated as true logical definitions, as for example in geometry, "two straight lines cannot enclose a space." Every new notion required its axiom. In passing from geometry to kinematics the idea of Time presented itself, and the appropriate axiom was contained in Newton's first law. On approaching dynamics Force and Mass were met with. He disagreed with Prof. Minchin in regarding force as most fundamental. Mass was more essential, for force might be abolished. On the other hand, he concurred with Prof. Minchin in thinking that the idea of a centre of mass was not axiomatic. Referring to Dr. Lodge's summary (NATURE, p. 62) he agreed with axiom (*a*) fully, and with (*b*) partially. Axiom 3 required further development. The crucial point, however, was axiom 4, "Stress cannot exist in or across empty space." This he regarded as very incomplete, and maintained that axioms defining the properties of the ether were necessary to further progress. If varieties of space be contemplated each advance required fresh axioms. Dr. C. V. Burton remarked that contact movement did not necessitate equal velocities; sliding motion was a case in point. Again, in deforming an incompressible fluid, although force and motion might exist, no work was done. Conservation could not be proved from denial of action at a distance. Speaking of the doctrine of transference and transformation of energy, he said it was a convenient working rule, but not true universally. Newton's laws were simple and consistent, but some doubt existed as to how much was definition and how much *law* or fact. Mr. Swinburne protested against the difference between theory and a working hypothesis being overlooked. All conceptions were based on experience, and ideas of ether and atoms derived from "jelly" and "cricket balls." We ought also to remember what "explanation" means, viz. describing the unfamiliar in terms of the more familiar. It was customary to describe the phenomena of fluids by reference to solids because we were more familiar with solids; an intellectual fish would probably do the reverse. The so-called "Theory of Magnetism" which breaks up a bar of iron into a number of small pieces, each possessing the properties of the original bar, he regarded as absurd. It was no "explanation" and not a "theory." Ether might be used as a working hypothesis, but must not be treated as an entity. Mr. Blakesley questioned whether transference of energy was always accompanied by transformation, and he did not see why energy should be looked upon as $(mv) \frac{v}{2}$, in preference to any other subdivision of the factors. As regards effects being proportional to their causes, he pointed out that the heating of an electric circuit, and thermoelectric action, followed laws not linear. Prof. S. P. Thompson, referring to the demonstration of the law of transference, &c., given on slip 8, said that attempts to translate it into Latin or Greek at once revealed the ambiguous character of the proof. Speaking of Ohm's law, he pointed out that R, a constant, was not an essential feature, as Dr. Lodge supposed. Ohm never said R was constant. In identifying energy, a difficulty presented itself, for one never came across it as a single thing but as a product, and in being transformed the paths of the two factors might possibly be different. Mr. Dixon said the whole of geometry and dynamics could be based on verbal definitions. The conservation of energy could be written as: Kinetic energy + potential energy = a constant, but on substituting the expressions for kinetic and potential energies, an identity resulted; therefore the original statement was not a law. Both the kinetic and potential energies of a system were functions of its configuration. Potential energy could not belong to a particle, but to a system. The president doubted whether Dr. Lodge's scheme was more simple, natural, and logical, than the ordinary one. The statement in NATURE (p. 62) that "strains were proportional to stresses" was simple enough, but it was questionable if "frequency of vibration is independent of amplitude" could be considered so. The author appeared to ignore *mass* in comparison with *force*, whereas the idea of *mass* seemed to be the more simple one. Dr. Lodge, in reply to Mr. Burbury, said two bodies never do attract one another; the thing which acted on either was the medium immediately in contact with it. Mr. Herroun had used metaphysical arguments against ether, but he (Prof. Lodge) thought it was a good thing to investigate ether. He agreed with what Prof. Minchin said about force and the first law of motion. *Force* was the more fundamental, but *mass* was best as a standard unit. As regards ether, he was prepared to say that it has no motion. It possessed electromagnetic kinetic energy, and probably all the stress energy that exists. Referring to the slipping body mentioned by Prof. Minchin and Dr. Burton he said that in speaking of the velocities of acting and reacting bodies being equal, he always meant that their velocities along the line of action were equal. The action between the sliding body and plane was a "catch and let go" one, like a fiddle bow and string. On the second laws of thermodynamics he hoped to say something in a subsequent paper. When he spoke of R being constant as the essence of Ohm's law he meant constancy as regards terms which appear in the equation $\frac{E}{c} = R$.

Linnean Society, June 1.—Prof. Stewart, President, in the chair.—Dr. J. Lowe gave an account of a newly-observed habit of the blackcap, *Sylvia atricapilla*, in puncturing the petals of certain flowers (*Hibiscus Rosa-sinensis* and *Abutilon frondosum*), specimens of which he exhibited, thus causing the exudation of a viscid secretion which proved attractive to insects upon which the bird preyed. The observations in question were made at Orotava, Teneriffe, during the month of March last.—By way of introduction to a paper by Mr. W. B. Hemsley on Polynesian plants collected by Mr. J. J. Lister, the latter gave an interesting account of the geology of the Tonga Islands, their volcanic nature, and the coral and limestone reefs with the soil formed chiefly of volcanic outpourings, on which dense patches of bush were growing. Referring then to the bird-fauna of the Tonga group, Mr. Lister compared it with that of Fiji and Samoa, and showed that it had no special affinity with the avifauna of New Zealand, and exhibited very little specialisation. Mr. Hemsley then gave an account of the plants collected there, as also in the Solomon Islands.—Mr. A. B. Rendle gave an abstract of a paper on fossil palms, in which his remarks were directed to a revision of the genus *Nipadites*, Bowerbank, and were illustrated by drawings of specimens from the London clay, Sheppey, from the Sussex coast, Selsey, Brussels, N.E. Italy, and elsewhere. The paper was criticised by Mr. Carruthers and by Mr. Clement Reid, who described the finding of specimens *in situ* at Selsey.—The secretary then read a paper by Dr. Baur on the temperature of trees, from observations taken in Colorado.—Mr. W. M. Webb gave an abstract of a paper on the mode of feeding in *Testacella*, illustrated by lantern slides prepared from original drawings of the living animal in various attitudes.

Royal Microscopical Society, May 17.—A. D. Michael President, in the chair.—Mr. G. C. Karop read a letter from Dr. R. L. Maddox on the subject of his rod illuminator.—A letter from Mr. W. H. Youdale, referring to some diseased beard-hairs, was also read by Mr. Karop.—Mr. C. Lees Curties exhibited and described a new form of camera lucida, made by Herr Leitz, of Wetzlar.—Sir David L. Salomons gave an exhibition with his projection microscope.—The President said they were extremely indebted to Sir David Salomons for the very admirable and interesting exhibition which he had given them, the value of which was not only on account of the defraction phenomena, which had been so well shown, but because of the advance which was indicated in the construction of the apparatus. He could not help observing, as the exhibition proceeded, that there was a remarkable flatness of field not generally seen under similar circumstances. There was one point on which he should like to ask for information; it sometimes happened that great concentration of light produced also a great concentration of heat, and that consequently objects in balsam, if exposed for too long a time, were apt to get spoilt through the softening of the medium. Was this difficulty got over in the present instance by using the electric arc light as an illuminant?—Sir David Salomons said he obviated it very much by using lenses cemented with balsam. The customary alum and water he found to be rather a trouble, and so he used simple distilled water, and found that it answered all the necessities of the case.

Zoological Society, June 6.—Sir William H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of May, 1893, and called special attention to a young Water-Buck (*Cobus ellipsiprymnus*), born May 4, 1893, being, so far as was known, the first antelope of this species that has been bred in captivity.—Mr. Walter Rothschild exhibited and made remarks on an egg of the Duckbill (*Ornithorhynchus anatinus*), taken from the pouch of the mother; the leg-bones and egg of an extinct bird of the genus *Æpyornis* from south-west Madagascar; and series of lepidopterous insects from Jamaica and from the Bolivian Andes.—Mr. Sclater exhibited and made remarks on some skins and skulls of mammals obtained in the Shiré Highlands by Mr. H. H. Johnston, Mr. B. L. Sclater, Messrs. Buchanan, and Mr. Alexander Whyte.—A communication was read from Messrs. F. E. Beddard and F. G. Parsons containing notes on the anatomy and classification of the parrots, based on specimens lately living in the Society's Gardens.—Mr. Sclater called attention to two front horns of an African rhinoceros belonging to Mr. F. Holmwood, which were stated to have been brought by native caravans from the district of East Africa, south of Lake Victoria Nyanza. They were remarkable for their great length and extreme thinness.—A communication was read from Mr. R. Lydekker containing an account of a collection of bird-bones from the miocene deposits of St. Alban, in the Department of Isère, France. The more perfect specimens were referred mostly to new species (*Strix sancti albani*, *Palæortyx maxima*, *P. grivensis*, and *Totanus majori*), while others were regarded as undeterminable from their fragmentary condition.—Mr. G. A. Boulenger read a paper describing some new species of reptiles and batrachians, based on specimens lately obtained in Borneo by Mr. A. Everett and Mr. C. Hose.

PARIS.

Academy of Sciences, June 5.—M. de Lacaze-Duthiers in the chair.—Note on the works of Comte P. de Gasparin, by M. Th. Schlœsing.—Researches on iron of Ovifak, by M. Henri Moissan. Three specimens of native iron, discovered by Prof. Nordenskiöld at Ovifak, Greenland, were tested for any crystallised forms of carbon they might contain. The first specimen had a metallic lustre, and was nearly black. This was found to contain a small quantity of the kind of graphite which swells up in boiling sulphuric acid. It also contained ordinary graphite distinctly crystallised, which gave rise to graphitic oxide on being treated with potassium chlorate. Fused potassium bisulphate dissolved all the residue. The second specimen also had a metallic lustre, but a light grey colour, and weighed 18 gr. After treating with hydrochloric acid the residue showed fragments of schreibersite, an opaque white mass of irregular form, and a large number of highly refracting grains. On treating this residue with hydrofluoric and then with boiling sulphuric acid the volume of the carbon increased, showing the presence of swelling graphite. No ordinary graphite was found. The third specimen, which consisted of metallic globules disseminated through a stony matrix, left after treatment with the three acids a residue containing some fragments of blue sapphire, which could be picked out with the forceps. Amorphous carbon was contained in all the specimens, swelling graphite in two of them, and ordinary graphite in one. Neither black nor transparent diamonds were found in any of them.—On the genesis of natural phosphates, especially those which have derived their phosphorus from organised beings, by M. Armand Gautier.—On the multiplicity of homologous parts in its relation to the gradation of vegetable species, by M. A. Chatin. The multiplicity of the homologous organs of a given apparatus is a certain sign of organic degeneration. The more numerous the homologous parts, the more they deviate from the verticillary type of floral organs and approach the spiral type. Their reciprocal symmetry is also less regular, and their position less stable. This view is confirmed by other incontestable signs of degeneration found to go together with multiplicity of homologous parts, and is illustrated by corresponding gradation in the animal kingdom, where the myriapod is classed below the hexapod insect.—On the repeated application of Bernouilli's theorem, by M. Jules Andrade.—On problems of dynamics reducible to quadratures, by M. Paul Staeckel.—Sketch of a new theory of electrostatics, by M. Vaschy.—On some phenomena exhibited by Natterer's tubes, by M. Gouy.—Absorption of seleniuretted hydrogen by liquid selenium at high temperatures, by M. H. Pélabon. If selenium be melted in a tube containing hydrogen and then cooled, it is found to contain a large number of bubbles with a brilliant internal surface, which are absent in selenium fused in air. On reducing the mass to powder the characteristic smell of seleniuretted hydrogen is observed, and if the mass is broken up under water the latter is coloured red by the finely divided selenium liberated from the seleniuretted hydrogen by the oxygen of the air.—Organometallic combinations belonging to the aromatic series, by M. G. Perrier.—On the coccidia of the birds, by M. Alphonse Labbé.—On the Plankton of the Polar Sea, by M. G. Pouchet.—On pseudo-fecundation in the Uredinei and accompanying phenomena, by M. Sappin-Trouffy.—On two cases of parasitic castration observed in *Knautia arvensis*, Coulter, by M. Molliard.—On the sedimentary strata of Servia, by M. J. M. Lugovic.—On the eclogites of Mont Blanc, by MM. L. Duparc and L. Mrazec.—On the employment of vine leaves for feeding cattle, by M. A. Muntz. In the south of France sheep are often let into the vineyards after the vintage and allowed to strip the vines of their leaves. The vines do not appear to suffer thereby in the least. Fresh vine-leaves contain 67·0 per cent. water, 18·5 extractive matter, 3·8 nitrogenous matter, and 2·3 per cent. fatty matter. When dried, the proportions are: extractive matter, 51 per cent.; water, 15; nitrogenous matter, 11; cellulose, 8·5; and fatty matter, 5·5 per cent. In the various vineyards of southern France the amount of leaves per hectare (2·47 acres) varies from 2500 to 9500 kgr., or about the average yield of hay for the same area. Moreover, the leaves, instead of getting blown away by the wind and lost, are converted into manure by the cattle, and, in addition, the vine is much less sensitive to drought than the ordinary fodder crops.—On the effects of inoculation of human cancer or cancerous products upon animals; positive result in one case, by M. Mayet.—On the amplitude and mean duration of the extreme oscillations of the barometer at Paris, by M. Léon Descroix.—On the density and alkalinity of the waters of the Atlantic and the Mediterranean, by M. J. Y. Buchanan. Along the entire south coast of Spain the water was of the same density as the Atlantic. Eastwards of Cape Gata, where the eastward current is no longer active, the denser water of the Mediterranean set in. The mean ratio of salinity and alkalinity was 0·50 for the Atlantic, and 0·4875 for the Mediterranean, the difference being probably due to the abundance of calcareous rocks on the latter.

AMSTERDAM.

Royal Academy of Sciences, May 27.—Prof. van de Sande Bakhuysen in the chair.—Mr. Hubrecht gave a description of phagocytic and vasifactive processes by which the trophoblast of *Tupaja javanica* attacks the maternal uterine epithelium and prepares congested surfaces against which the area vasculosa and afterwards the allantois are applied. The placenta of Tupaja is double, and situated right and left of the fœtus. The trophoblast of Tupaja was furthermore compared to that of Sorex and of Erinaceus, in all of which it displays a considerable degree of activity. It was more rigorously defined as being the epiblast of the mammalian blastocyst, after deduction of what is intended for the formation of the embryo and for the internal coating of the amnion. In conclusion, certain phylogenetic speculations concerning the trophoblast were brought forward.—Mr. Schoute exhibited three new thread-models of developables related to higher algebraical equations. The first is the discriminant of the general cubic $u^3 + 3xu^2 + 3yu + z = 0$. It divides space into two parts, corresponding to points with 3 or 1 real roots. The ordinary twisted cubic forms its cuspidal edge. The discussion of the number of real roots situated between two given limits is facilitated by means of a certain tetrahedron. The second surface corresponds to the quartic $u^4 + 6xu^2 + 4yu + z = 0$. It divides space into three parts, containing points with 4, 2, or 0 real roots. By planes perpendicular to the x-axis it is cut in rational quartics with two cusps and one node. It possesses a parabolic nodal curve. And the third model realises the surface corresponding to the sextic $u^6 - 15u^4 + 15xu^2 + 6yu + z = 0$. It divides space into four parts, with points admitting 6, 4, 2, or 0 real roots. Any plane perpendicular to the x-axis meets it in a rational sextic curve with four cusps and six nodes. The cusps of the cuspidal edge are very remarkable points on this surface. In general the developable corresponding to a likewise mutilated equation of the nth order with three coefficients x, y, z, will show rational sections of the nth order with the planes perpendicular to the x axis, admitting $n - 2$ cusps and $\frac{1}{2}(n - 2)(n - 3)$ nodes, &c.—Mr. van der Waals gave a formula for the law of molecular force. By putting

$$-f\frac{e^{-\frac{r}{\lambda}}}{r}$$

for the potential of two material points, all the known laws of molecular action may be deduced. In this formula λ is a line equal to the quotient of La Place's H and K. This law may be explained by supposing (1) that the action of the point itself varies inversely as the square of the distance, (2) that the universal medium gradually does absorb the lines of force.

BOOKS, PAMPHLETS, and SERIALS RECEIVED

BOOKS.—Mensuration of the Simpler Figures: W. Briggs and T. W. Edmondson (Clive).—Science Teaching in Schools: H. Dyer (Blackie).—New South Wales Statistical Register for 1891 and Previous Years: T. A. Coghlan (Sydney, Potter).—Conquête du Monde Végétal: L. Bourdeau (Paris, Alcan).—A Popular History of Astronomy, 3rd edition: A. M. Clerke (Black).—Problèmes et Calculs Pratiques d'Électricité: A. Witz (Paris, Gauthier-Villars).—Captain Cook's Journal, edited by Captain Wharton (E. Stock).—Bionomie des Meeres; Erster Theil—Einleitung in die Geologie als Historische Wissenschaft: J. THURSDAY, JUNE 22, 1893.

THE THEORY OF FUNCTIONS.

Theory of Functions of a Complex Variable. By Dr. A. R. Forsyth. (Cambridge University Press, 1893.)

WHAT is the theory of functions about? This question may be heard now and again from a mathematical student; and if, by way of a partial reply, it be said that the elements of the theory of functions forms the basis on which the whole of that part of pure mathematics which deals with continuously varying quantity rests, the answer would not be too wide nor would it always imply too much.

It cannot be denied that the teaching of pure mathematics in this country has followed curiously restricted lines. While in geometry and the theory of forms the student has for many years past had the advantage of excellent English text-books, the general theory of functions has been entirely unrepresented till the appearance of the treatise whose title stands at the head of this notice. Of treatises on special classes of functions, if we omit those written purely with a view to applications, Cayley's "Elliptic Functions," published in 1876, is the sole representative; while till last year there was no work on the theory of numbers. The theory of groups, and its applications to the theory of equations, is still unrepresented in native English mathematical literature, though here we have the translations of Prof. Klein's "Vorlesungen über das Icosaeder," and Herr Netto's "Substitutionentheorie," published, the one in 1888, and the other last year. At Cambridge, and probably to a great extent in other centres, the teaching and the course of study of individual students have tended on the whole to follow the lines of the available English text-books, and where these have been incomplete or entirely wanting there has, till very recent years, been no sufficient introduction to the corresponding subjects.

Why a subject of such fundamental importance for the advancement of pure mathematics as the theory of functions should have happened to fall into this latter class, it is not easy to tell. It may be said to have been first put on a secure footing by Cauchy's great memoir on integrals taken between imaginary limits, which was published in 1825. Many advances were made by a number of eminent mathematicians in the following years, and the study of the subject received a great impetus from the new and very fascinating method of presenting it which Riemann gave in his famous memoirs on the theory of functions of a complex variable (1851), and on the theory of the Abelian functions (1857).

Weierstrass and his pupils, again, developed their theory from a standpoint which is essentially distinct from that of either Cauchy or Riemann. The growth of the subject during the last thirty years has been remarkable, and it is probably safe to say that the foreign literature of the subject is now more extensive than that of any other branch of pure mathematics. The number of text-books that have been published directly on the subject is wonderful in itself, and more so when it is remembered that almost every foreign treatise on the Differential and Integral Calculus contains some introduction to the theory of functions.

If there is any justice in the preceding remarks, the want of a treatise on this subject has too long caused a serious gap in our mathematical literature; and it may be at once said that Dr. Forsyth's book supplies that want so completely that it is not likely to be felt again for a long time to come.

Among the large number of foreign treatises above referred to are several which, in their own line, it would be difficult to improve upon; but they all, or nearly all, deal with the subject from a single point of view, being indeed written with that intention. Dr. Forsyth, on the other hand, has aimed at giving a complete introduction to the theory; and it may safely be said that, with his book as a guide, the task of the student who wishes to enable himself to follow its various recent developments will have lost half its difficulty.

The bringing of the various parts of the subject, and the different points of view from which they may be approached, into their proper connection with each other has here been done in the most masterly way; while though Dr. Forsyth expressly disclaims in the preface to have dealt at length with anything but the general theory, he has carried the developments of the subject in the direction of doubly-periodic and allied functions, Abelian integrals, and automorphic functions to a point from which the student can have no difficulty in passing on to the study of any recent work done in these branches.

It is impossible in the limits of a short article to give any complete account of a book extending to over 700 pages, but some attempt may be made to describe the order of treatment. The first four chapters are devoted to the simpler properties of uniform functions, their expansion in power-series and their integration. Chapters v., vi. and vii. deal with uniform transcendal functions, giving the principal results of the investigations of Weierstrass and Mittag-Leffler. In this connection the very remarkable result due to Weierstrass is given, which is expressed by him in the following words:—"Dass der Begriff einer monogenen Function einer complexen Veränderlichen mit dem Begriff einer durch arithmetische Grössenoperationen ausdrückbaren Abhängigkeit sich nicht vollständig deckt." The writer of a recent criticism in this journal would probably say that this statement deals only with the morbid pathology of mathematics; but the pure mathematician at all events should surely know, as far as possible, what is implied in the word function.

Non-uniform functions are introduced in chapter viii. They are regarded, to begin with, as arising from the various continuations of a power-series, the most general point of view that can be taken; Riemann's method of dealing with algebraic functions and their integrals not being introduced till considerably later. The following chapter deals with the integrals of non-uniform functions; and from the particular examples given arise some of the simplest singly- and doubly-periodic functions, whose properties, when uniform, are discussed in Chaps. x., xi., and xii. This part of the subject aptly ends with a demonstration, due to the author, of the theorem that if $f(u)$, $f(v)$, and $f(u+v)$ are connected by an algebraical equation with constant coefficients, $f(u)$ must be either an algebraic, a simply-periodic, or a doubly-periodic function of u. The proof of this important theorem by

Weierstrass, to whom it is due, has never been printed; and the only published proof, besides the one which Dr. Forsyth gives, appears in a paper by M. Phragmen in vol. vii. of the "Acta Mathematica," and is on entirely different lines. Whether either proof is entirely satisfactory is a point on which differences of opinion may conceivably occur, though of course there is no doubt as to the truth of the theorem itself.

Chap. xiv., which is headed "Connectivity of Surfaces," is purely geometrical, and strictly has nothing to do with the theory of functions. It was however necessary for the author to introduce such a digression if the following chapters dealing with Riemann's theory were to be understood, since there is no treatise to which reference could be made for the various theorems and results that have to be used. The chief properties of a Riemann's surface, regarded as arising from an algebraical equation between the variables, are discussed in Chap. xv. Though there is no difficulty in conceiving the geometrical nature of a Riemann's surface from a description, the relation between the surface and the set of functions (algebraische Gebilde) whose study it is intended to simplify is not so readily grasped at first by the student; and it would not perhaps have been amiss to have dealt with this relation in one or two simple cases, at some length, as an introduction to this part of the subject. In Chap. xvi., the surface still being regarded as defined by a given equation, the properties of uniform functions on the surface, and of their integrals, is investigated.

From this point to the end of the book we have to do, more or less directly, with the fundamentally new conception of Riemann which has been so wonderfully developed during the last ten or fifteen years. The Riemann's surface, as defined by a given equation, affords a most convenient means of study of a system of connected functions. Suppose, however, the surface to be given quite independently of any equation. The possibility at once suggests itself that the surface may serve as the definition of a set of connected functions. Riemann's own demonstration that this is the case has since been shown to be faulty, but the conception is an invaluable one, and it has been placed on a secure foundation by Schwartz (and others), by means of the so-called existence theorem. Chap. xvii. is entirely occupied with the proof of this theorem, and in Chap. xviii. follow the investigations with respect to the form and nature of the integrals and uniform functions, so shown to exist, on a Riemann's surface given arbitrarily.

Chaps. xix. and xx. deal at length with the theory of conformal representation. This forms one of the most obviously interesting parts of the subject, and is also one of those which lend themselves most readily to the purposes of application; and it is to be noted that, although owing to necessities of arrangement these chapters occur near the end of the book, the author suggests that, on a first reading, Chap. xix. should be taken at an early stage.

The last chapter in the book gives an introduction to the theory of automorphic functions, the previous one being taken up by a necessary digression on groups of linear substitutions. Dr. Forsyth follows M. Poincaré in actually obtaining analytical expressions for the functions in the form of the ratio of infinite series, analogous to the expressions for elliptic functions as ratios of the theta-functions. These analytical expressions, though of great interest, are too complicated in form to be readily used for deducing the properties of the functions they represent, so that their properties must be inferred from their quasi-geometrical definition by means of a "fundamental region"; and this is essentially the method of dealing with them used by Prof. Klein.

In thus shortly stating the contents, or rather the headings, of the successive chapters some risk is run of representing the book as a mere compilation. Nothing could possibly be further from the truth. From the nature of the case it is inevitable that the greater portion of the book should be taken up with detailing the results of other writers, but Dr. Forsyth has done this in a most independent way. The book is instinct all through with an original spirit; in numerous instances, where clearness or conciseness were to be gained, the author has modified or completely altered the usually-given proofs, while, as has been already stated, the various parts of the subject have been brought together, and the many different ways of dealing with them have been used, in such a way that the theory is presented to the reader as a connected and harmonious whole. Dr. Forsyth is to be warmly congratulated on having brought to so successful a conclusion what must have been an extremely arduous task. If it is not ungracious to "ask for more" so soon, we may express the hope that he will now go on to deal, as completely and successfully, with functions defined by differential equations.

The book itself is beautifully printed and the figures, many of which must have required careful drawing, are well reproduced. The table of contents is sufficiently complete to form a sort of *précis* of the whole; and lastly, we have to be grateful for three separate indices. The first of these, an index to all the technical terms used in the book, whether English or foreign, is a most useful addition; especially for those who wish to use the book without reading right through it. W. BURNSIDE.

TINCTORIAL ART AND SCIENCE.

A Manual of Dyeing: for the use of Practical Dyers, Manufacturers, Students, and all interested in the Art of Dyeing. By Edmund Knecht, Ph.D., Christopher Rawson, F.I.C., and Richard Loewenthal, Ph.D. (London: Charles Griffin and Co., 1893.)

THE present work consists of three volumes, two of letterpress, interspersed with illustrations of plant, which run to over 900 pages, and a third volume containing specimens of dyed fabrics. It is a substantial contribution to an important branch of technology, and the authors have succeeded fairly well in meeting the requirements of the various classes of readers for whose use the work has been written. The first general impression produced on looking through the volumes is one of satisfaction that the subject is handled in a more scientific way than has hitherto been the case in such works. The only feeling of disappointment to which the consideration of the book gives rise is in no way attributable to the authors, but is due to the circumstance that so little is known about the scientific relationship between a colouring-matter and the fabric which is dyed thereby. All that is known about the theory of dyeing is ably stated in the introductory chapter, and one of the authors (Dr. Knecht) has himself made some very interesting investigations in this field. But, in spite of all that has been written, the subject of dyeing has still to be taught as an art rather than as a science. The centres of the tinctorial industry in this country, such as Leeds, Manchester, Bradford, and Huddersfield, are now provided with Technical Schools, in which the dyeing department is made a special feature. If we might venture to offer a word of advice to those who are providing for this industry, it is that adequate provision should be made for the scientific side of the subject by the equipment of laboratories and the appointment of competent specialists for carrying on original investigation in connection with dyeing. The dyeing departments in those schools which we have had the opportunity of visiting are admirably equipped for instruction in the principles of the art, but the instructor has to devote so much time to this part of the work, and the students who attend are, as a rule, so ill-prepared in general scientific training that the instruction given cannot rise much above that handicraft level against which the writer has had so frequently to protest in connection with other branches of technology. Till this defect is remedied, the results achieved by our technical schools will not be commensurate with the endowment bestowed upon their equipment.

The work which has given rise to these reflections will go far towards placing the tinctorial art on a higher scientific level. It is not, as the authors state in the preface, "a mere 'cookery-book,' containing 'rule of thumb' recipes." A detailed analysis of its contents would be out of place in these columns, but a general idea of its scope may be given. The introductory chapter, as already stated, deals with the theory of dyeing. So far as wool and silk fibres are concerned, the authors consider that the evidence is in favour of a chemical as opposed to a purely mechanical explanation :—

"According to the mechanical theory, wool dyed with magenta, for instance, would simply absorb the unchanged hydrochloride of the dyestuff, and thus assume the same colour in the solution of the dyestuff. But experiment has shown that this is not the case. It absorbs the colour base, which is, however, in itself colourless. Where then does the colour come from? We can come to no other logical conclusion than that the colour base has combined chemically with some constituent of the fibre to form a coloured salt."

But this explanation does not enable us to see how the dyed "constituent" is combined with the other constituents of the fibre :—

"This objection is easily met by assuming that what is taken up *is* in chemical combination with some insoluble constituent of the fibre and is held by the rest of the transparent or translucent substance of the fibre in a state of *solid solution*."

Thus the theory advocated is partly chemical and partly in that debateable region where chemistry and physics have recently come into apparent collision. Researches in connection with the theory of dyeing have more than a purely technical value, and we hope that Dr. Knecht will continue the good work which he has commenced. With respect to cotton the authors state :—

"With the large numbers of direct cotton colours which are placed at our disposal, and which are continually increasing in number, the question becomes more and more important from a theoretical point of view. It is not probable that it will ever be solved by vague theoretical speculations based on one or two known facts. In all probability the solution of the question will require much laborious work, including many quantitative determinations."

The technical part of the work begins with Part II., dealing with the textile fibres of vegetable and animal origin, such as cotton, flax, hemp, jute, China grass, wool, silk, &c., not omitting Chardonnet's artificial "silk" prepared from nitrated cellulose. The third part is devoted to water from the dyer's point of view, and the fourth part to washing and bleaching. Parts V. to VIII. deal with the materials used in dyeing. All these materials are classified into the three groups, Chemicals, Mordants, and Dyestuffs, and are described under the collective (and most objectionable) name of "drugs." The acids and alkalies employed by the dyer are first treated of, then the mordants, which are discussed in a very thorough manner, no less than 150 pages being devoted to them. Three parts (VI., VII., and VIII.) are devoted to the natural, artificial organic, and mineral colours respectively.

The machinery used in dyeing forms the subject of Part IX., the investigation into the tinctorial properties of colouring matters that of Part X., and the concluding part treats of the analysis and valuation of the materials used by the dyer. There is an appendix of miscellaneous subjects such as weights and measures, thermometer scales, specific gravities, light and colour, &c.

The foregoing synopsis of its contents shows that the work is well calculated to fulfil the object which the authors had in view, viz. to serve "as a book of reference or *vade mecum* to the educated dyer." But it is not really for an individual class that this book is written; it appeals to several distinct kinds of readers. It may safely be asserted that there are few, if any dyers, in this country, however "educated," who could with equal intelligence follow every section of the work under consideration. The practical dyer who is most skilful in applying colouring matters to fabrics is generally hazy in his notions of chemistry, and absolutely ignorant so far as concerns the finer questions of the "constitution" of the complex products which chemistry has placed at his disposal. In order to understand properly the chemical portions of this manual a very sound foundation of chemical science must have been previously laid. On the other hand, a person who is thoroughly acquainted with the chemistry of dyestuffs would be worse than useless—he might be actually destructive—in the dye-house unless he had been trained in the application of colouring matters on a large scale. We are sometimes told that the practical dyer need know nothing of chemistry; that he would not do his work any better when possessed of such knowledge. There are still to be met with here and there so-called "practical" men who go further and assert that the possession of too much chemical knowledge would unfit the dyer for his work. But public opinion appears to be undergoing a healthy change in this as in other departments of technology. It may be long before we produce the ideal technologist who is equally acquainted with the chemical nature of his materials and the mechanical methods of applying them. It appears, however, that this combination of knowledge is just what is wanted in the industry. The joint authorship of the present manual perhaps supplies the best illustration of this principle that could be furnished.

A word or two as to the illustrations, of which there are no less than 116 incorporated with the text. We notice with some regret the prevailing fault so common in technical manuals: no scale of size is in any case given. This perhaps is of no consequence to the practical dyer who is already acquainted with the "plant," but as the work is also intended for students the omission is serious. Much of the machinery also is of foreign make; it is to be hoped that this has not the same significance as the fact that by far the greater number of artificial colouring matters described in the seventh part are of foreign manufacture. In the art of dyeing this country still holds a very good position, and it is satisfactory to find that the authors have not had to go outside Yorkshire for the dyed patterns forming the third volume of their work.

Perhaps the best recommendation that we can offer in favour of the present manual is that there is nothing which in our opinion calls for very serious criticism. The chemical formulæ might, in many cases, have been more economically packed; in some instances "bonds" have apparently dropped out (benzoflavine, p. 469; nile-blue, p. 486, and the oxazines generally; anthracene, p. 577, &c.). The authors formulate the so-called "bicarbonates" on p. 68 on the type $M''O(CO_2)_2$. The utility of the third volume would have been much enhanced if the pattern sheets had been paged and indexed separately, so as to have facilitated reference to any particular pattern. The appendix on light and colour (p. 881) wants amplifying in view of the importance of this subject to the tinctorial industry, and some account of Abney's researches on colour should have been given. This section would also have been made more intelligible by the introduction of a few illustrations of absorption spectra and the practical method of mapping them.

About seventeen years ago we had occasion to notice a work of a somewhat similar nature in these columns (vol. xiii. p. 283). No more striking illustration of the advancement in the art of the dyer could be furnished than by comparing that work (Crace-Calvert's "Dyeing and Calico Printing," by Stenhouse and Groves) with the "Manual" of Dr. Knecht and his colleagues. Other works have appeared since that time, some of real value, others mere compilations pandering to the examination fetish. It would be invidious to institute comparisons; suffice it to say that the present work will compare favourably with any treatise in this department of applied science.

R. MELDOLA.

A NEW MANUAL OF BACTERIOLOGY.

A Manual of Bacteriology. By George M. Sternberg, M.D., Deputy-Surgeon-General U.S. Army. (New York: William Wood and Co., 1892.)

A YOUNG and rapidly-growing science continually demands a series of new text-books for the use of those students who would keep themselves abreast of the times, and it is, perhaps, inevitable that, with the growth of knowledge, the text-books should assume more and more alarming proportions. The present work—a portly tome of nearly nine hundred pages—comes to us from across the Atlantic as the latest, the largest, and, let us add, the most complete manual of bacteriology which has yet appeared in the English language. The volume combine in itself not only an account of such facts as are alread established in the science from a morphological, chemica and pathological point of view, discussions on suc abstruse subjects as susceptibility and immunity, bu also full details of the means by which these results hav been obtained, and practical directions for the carryin on of laboratory work. It is thus, as stated in the pre face, at once a manual for reference, a text-book fo students, and a handbook for the laboratory. And i the mind of the reader there may arise the questio whether the attempt to combine the three has no resulted in a volume of somewhat too portentous a size.

Dr. Sternberg is well qualified for the task he ha undertaken. Himself a well-known worker in bacterio logy, and director of the Hoagland Laboratory i Brooklyn, his work is no mere compilation of the result of others, but embodies also the fruits of his own origina thought and observation. The amount of labour involve in bringing together from the literature of differer countries the facts necessary for a manual of this kin may be estimated from the fact that the bibliograph alone fills over a hundred pages and contains 258 references. The illustrations are numerous, clear, an accurate; many of them are printed in colours, and ther are some good reproductions of microphotographs.

The work is practically divided into four parts, an of these the first is mainly occupied by an account o methods and of practical laboratory work, preceded b short sections on the history of the subject, on classif cation, and morphology. These are clear and concis the basis of classification adopted being practically tha of Baumgarten, in which the different genera are groupe under the three main headings of "micrococci," "bacilli, and "spirilla." The practical directions include stainin methods, the preparation and sterilisation of cultur media, and the various modes of cultivation, togethe with directions for experiments on animals. These sul jects are dealt with very fully, and will be found to em brace all that can be required for laboratory work. short section on microphotography concludes this par Many English ears will resent the term "stick-culture which is used as the equivalent of the German "stic cultur"; and, indeed, in other instances it would hav been possible to employ more euphonious translations o the original German terms. It may also be noted th in describing Chamberland's filter that gentleman's nam is incorrectly spelt in every instance.

The second portion of the book deals with the biolog and chemistry of bacteria, and the important subject o disinfection and antiseptics. Details are given of th modifications which may be artificially induced in th biological characters of bacteria, and especially of tho by which attenuation of virulence can be produced i pathogenic species. The section on the products of vit activity contains an account of the various fermentatio and decompositions known to depend on bacterial actio and is followed by one on the ptomaines and toxalbumir produced by certain species. The subject of disinfecti is then treated at some length, embracing a descriptio of the effects on micro-organisms of dry and moist hea of acids, alkalies, various salts, and coal-tar product which is fully up to date and leaves little to be desire The whole concludes with a useful summary of means practical disinfection, based mainly on the report of the Committee on Disinfectants of the American Public Health Association.

The third part, the most important division of the book, deals with pathogenic bacteria in detail, and is prefaced by a description of their modes of action, and of the ways in which they may gain access to the system. Here too we find a discussion on the difficult subjects of susceptibility and immunity, to which indeed Dr. Sternberg has elsewhere made important contributions. The discussion is lengthy and impartial, and well deserves careful reading. Relying on recent experimental evidence, the author reaches a guarded conclusion that acquired immunity depends on the formation of antitoxins in the bodies of immune animals. Subsidiary weight is given to the view, which he formerly upheld, that the cells of the body may acquire tolerance to the toxic products of pathogenic organisms, and also to the doctrine of phagocytosis, to which he gives a partial assent. A recent lecture by Metschnikoff on the latter subject is reproduced *in extenso*. It is impossible here to follow in detail the descriptions of the different pathogenic bacteria. The order in which they are discussed is necessarily somewhat arbitrary, but is convenient, and follows the broad grouping into micrococci, bacilli and spirilla. Amongst the pyogenic organisms Fehleisen's *Streptococcus erysipelatos* is frankly placed as identical with *Streptococcus pyogenes*, an arrangement with which many will not agree. Altogether no less than 158 organisms are described as pathogenic for man or the lower animals, and according to their relative importance the descriptions are in large or small print—an arrangement convenient for the student. A section follows on bacteria in diseases not clearly proved to be of bacterial origin, and the whole concludes with a classification of pathogenic organisms from a pathological standpoint.

The fourth part of the book deals with saprophytic bacteria, special chapters being devoted to bacteria in air, in water, in soil, in or on the human body, and in food. The total number of saprophytes described is 331. The merit of a work of this kind depends less on the number of species described than on the clearness and accuracy of the descriptions, and Dr. Sternberg has spared no pains to make these as complete as possible. To facilitate the recognition of species a chapter on bacteriological diagnosis has been added, in which the different organisms are grouped according to their form, cultural characters, and other peculiarities. This section will be an important aid to the student in identification. A lengthy and well-classified bibliography brings the work to a conclusion, and the whole is well indexed. The author is to be congratulated on the success with which he has accomplished a difficult and laborious task.

TEXT-BOOKS OF ZOOLOGY.

Lehrbuch der Zoologie. By Prof. Richard Hertwig, of Munich. (Jena: Gustav Fischer, 1891.)

Zoology of the Invertebrata. By Arthur O. Shipley, Fellow of Christ's College, Cambridge. (London: A. and C. Black, 1893.)

IT is a difficult matter to say much that is readable about text-books which are produced by teachers with a view to the limited requirements of their own pupils. Some text-books are, so to speak, obviously addressed to the world—are intended by their authors to be consulted both by the advanced student who is himself a teacher, and by all serious followers of the science dealt with. Others have their justification in being epitomes of a professor's or lecturer's teaching, suitable to his immediate pupils. The former class challenge criticism, and have a high standard of interest; the latter class are hardly fit subjects for appreciation, and possess a very limited importance.

Prof. Hertwig's text-book of Zoology is one which will no doubt be found serviceable by his pupils, and by the younger students of German universities. It is constructed on the usual lines, and contains nothing either in treatment or illustration which the author would probably wish to submit to his colleagues as novel or important. It has not the stamp of originality and freshness which gives a character and significance to Prof. Berthold Hatschek's unfinished text-book. It is well illustrated by the aid of the new "process" methods, and must be estimated as much by the judgment displayed in the omissions necessary in so condensed a work as by the actual statements which it embodies. The latter are, though not novel, sufficiently up to date.

Mr. Shipley's book on the Invertebrata appeals to an even more limited circle than Prof. Hertwig's. Professedly it is addressed to those who only wish to learn a very little about zoology, and who will be content to dispense with all bibliography, and even with reference to the names of authorities for the statements and for the systems of classification which Mr. Shipley incorporates as accepted fact. Presumably Mr. Shipley's book is intended for Cambridge students who take zoology in Part I. of the Tripos, and do not proceed to Part II. The book will no doubt prove useful to these students. To others, a more critical, more comprehensive, and more authoritative treatment of the subject must be recommended. To those who are not acquainted with special circumstances which may have determined the author's procedure, it must appear a matter for regret that when producing a volume so well printed and largely illustrated he did not make it more thorough. It is not possible to discuss the opinions adopted by Mr. Shipley upon several questions of interest, because he himself does not treat them argumentatively, but rather as matters of information to be accepted by the pupil from his tutor. Zoology, when deprived both of history and of argument, is singularly uninteresting, and will perhaps in this shape gain approval as a subject of school-education.

E. RAY LANKESTER.

OUR BOOK SHELF.

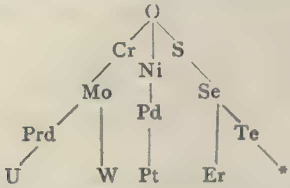
Das Genetische System der chemischen Elemente. Von W. Preyer. (Berlin: R. Friedländer und Sohn, 1893.)

THE treatment of the material contained in this book is based on the idea that the elements have been produced from hydrogen, or ether, or primordial matter, by a process of condensation.

The fourteen horizontal rows of the periodic table are regarded as representing fourteen different degrees of condensation of the initial substance, and the rows are then connected together so that they fall into five different groups, each of which group constitutes a generation.

The system works out in such a way that each element in the first row of the periodic table becomes the parent of all the elements in its own vertical series.

Oxygen, for instance, is the root of the following geneaogical tree:—



Chromium, nickel, and sulphur, in this way belong to the second generation. Molybdenum, paladium, and selenium to the third generation, and so on. The constants of the elements, such as atomic weights, densities, atomic volumes, specific heats, atomic heats, and their electrical and magnetic properties, their valency, &c., are then discussed with the view of justifying the mode of treatment adopted. It is here shown that on arranging the elements according to the author's system, besides the well-known relations between properties and atomic weights, additional simple numerical relations are traceable between the magnitudes of the atomic constants themselves, and also between these magnitudes and the numbers denoting the degree of condensation of the groups to which the elements belong. The use to which these may be put as a means of controlling the values of atomic weights and predicting the properties of undiscovered elements is indicated.

The second and not the least useful part of the book contains a collection of physical constants, from which the data used in the first part were chosen.

The book is a suggestive contribution to the literature on a subject which since the time of Prout has been prolific of speculation, but which even yet seems slow to condense and take a form sufficiently definite to warrant its being raised to the rank of a theory. J. W. R.

The Future of British Agriculture. By Prof. Sheldon. (London: W. H. Allen and Co., Ltd., 1893.)

THE opening chapters of this little book are devoted to the solution of the questions, "Will wheat-raising pay in Great Britain?" and "Is wheat to be no longer king?" After indicating the reasons which led to the enormous reduction of land under wheat—a decrease of something like 42 per cent. within the last twenty-five years—Prof. Sheldon comes to the conclusion, that, notwithstanding the importation of foreign wheat, and the fact that an ever-increasing demand for milk (of all farm products the least suitable for importation) necessitates larger areas of grass land, wheat-growing will not only continue, but may soon reach its former position, an event which he would not consider to be "a sign of unadulterated good." In connection with the question of wheat-production in the United States, there is one statement, made on the authority of leading American statistical experts, which we venture to think requires qualification, namely, "that in less than twenty years from 10 to 15 per cent. of the people's food will have to be *imported* into the United States." This is a point on which there may well be diversity of opinion, but, as pointed out by Messrs. Lawes and Gilbert in their recent paper on "Allotments and Small Holdings," the conditions will be quite changed with increased population, rotation will gradually become general, yielding various food products for home consumption; the soil will be better cultivated, yielding much larger crops of wheat where it is grown; straw and manure will no longer be burnt or wasted; and, lastly, there are still considerable areas of rich prairie land to be brought under the plough. So that it is probable that increased density of population will less rapidly diminish the capability of production for export than may, at first sight, be supposed.

Perhaps the most interesting chapters are those on dairy farming; and it will afford a good deal of consolation to the dairy farmers of this country to learn that Prof. Sheldon believes "the competition of the United States is within measurable distance of its limit."

The book concludes with a chapter on a most important subject—tenant farmers' interests. The author states his view of the matter in his usual clear and forcible manner, and incidentally refers to what he terms "exploded, impossible 'Protection'," and to "that new economic craze, 'Bimetallism'."

We welcome the book as a valuable contribution to our agricultural literature, and as a useful guide to those branches in which the author is especially qualified to instruct.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Mr. H. O. Forbes's Discoveries in the Chatham Islands.

I WRITE a final line on this subject to express my regret that I should have misunderstood Prof. Newton and attributed to him (NATURE, p. 126 above) opinions in regard to the relationship between *Erythromachus* and *Aphanapteryx* which he does not hold.

On a point of accuracy, however, in regard to the "slight confusion of dates," allow me to say that I am sure no one will admit more readily than he that this had occurred, when I remind him of his letter to me of December 22, 1892 (now before me), in reply to a note of mine requesting him to be so good as to repeat his suggestion in regard to the name for the new genus, which I was about to describe, as I had mislaid his former note. "I have no memorandum," he says, "of what I suggested to you, but only an indistinct recollection that it was *Diaphorapteryx* . . . or something like that." This was, therefore, the date of the re-suggestion, and not my visit to Cambridge on February 23, 1893. *Diaphorapteryx* was described as a new genus in the Bull. Brit. Ornith. Cl., December 31, 1892.

HENRY O. FORBES.

The Fundamental Axioms of Dynamics.

A VERY brief reply to such of your correspondents as have favoured my paper with direct or indirect criticisms will at the present stage of the discussion be sufficient.

Referring first to Prof. Rücker's letter on p. 126, I acquiesce in the greater part of it—especially in its concluding paragraph, but it may clarify matters if I explain (1) that I do not contemplate *parts* of the ether, but regard it as an absolute *continuum*. Not the slightest advantage is gained by pushing action and distance back a step or two—it must be exterminated. (2) That I have no faith in "action at constant distance" other than distance zero. The reason such a phrase ever appeared in my papers is because that is all I am able to deduce from the assumption of the conservation of energy. It requires identity of energy to prove absolute contact. Hence I prefer to work backwards, and, assuming universal contact action or the denial of action at a distance, to deduce therefrom both the conservation and identity of energy.

Prof. McGregor contradicts three statements in the Report of the meeting of the Physical Society (p. 117), a report which is usually admirably done, and which was well done in this case. Though not responsible I reply to his three points categorically:

(1) He was *understood* to object to the Newtonian statement of the first law—not to the fact or law itself.

(2) A reference to the first two pages of his paper in the February *Phil. Mag.* will show him, I think, that he has now partially forgotten what he said on the second head.

(3) It is to be admitted at once that the phrase "equally well," not "well," was employed.

Now, turning to Mr. Dixon's letter (p. 149), it does not seem to me that he is perfectly candid. He accuses me in his concluding paragraph of an unfair practice by omitting the word "direct," but no such word occurred in his letter on p. 103, to which I was replying; nor is what he now says consistent with the surface meaning and intention of the second paragraph in his former epistle, so far as I can judge. A withdrawal of that hasty and misleading paragraph is what I had expected from him.

In the first paragraph to his recent letter he explains why he considers that the fact that potential energy belongs to a system is hostile to the idea of identity, but his proof does not appear to me valid unless the phrases "belongs to" and "has no local habitation within" are considered identical. If he can show that a given portion of potential energy "has no local habitation within a system," he will undoubtedly be usefully attacking the proposition that it possesses identity, but I do not see that he has even attempted such a proof at present.

OLIVER LODGE.

Popular Botany.

I VISITED Tyne Dock yesterday, in order to attempt to solve the question put by Mr. A. W. Bennett in your issue of the 1st inst.

The plants which caused the fatality grow in a small hollow close to a newly-opened road. The surviving child is but five years old, and therefore much too young for any evidence of hers to be convincing.

There seems little doubt, however, that the hemlock, *Conium maculatum*, brought about the death of the other two children. Large quantities of this, looking very attractive just now, are growing on the spot, together with smaller quantities of *Heracleum sphondylium*, *Anthriscus sylvestris*, and a very few plants of *Bunium flexuosum* at the margin of the hollow. No other umbelliferous plant is growing near. Yesterday, troops of children were gathering the young and pretty leaves of the hemlock, and making them up into bouquets with grasses and flowers.

The children, who died from the effects of eating the plant were aged respectively four and five years, and probably, in common with thousands of others in the district, would not recognise cabbage if they saw it growing, which very likely they never did. I have met many very much older children here who are as ignorant of common garden and field plants.

Gateshead-on-Tyne, June 12. JOHN BIDGOOD.

The Big and Little Monsoons of Ceylon.

IT is well known to all Anglo-Indians, even the least scientific, that the summer monsoon is ushered in by two periods of rain-burst, called respectively the chota and burra barsât. The former occurs sometimes in April or May, and the latter in June or July, the precise dates varying not only with the locality but with the year. The chota barsât only lasts a few days, and is looked upon as the advance guard of the burra barsât, or great rains.

The conditions which tend to produce the chota barsât have not, so far as I am aware, been studied in detail, but are probably similar in character though on a smaller scale, and more local than those which regulate the inception of the burst of the monsoon, as it is popularly termed. It can be readily understood that as soon as the solar rays are sufficiently powerful to heat up a portion of the land area, and by lowering the pressure to determine an inrush of surrounding marine air, condensation and precipitation will occur much in the same way as in the burra barsât when the air over the whole peninsula has become heated, and the saturated air from the equatorial Indian Ocean rushes in in a large and continuous stream towards the low pressure area thus formed. In the former case the conditions are not only more local and ephemeral owing to the small amount of vapour formed over a comparatively cool sea, but are mixed up with the residue of the cold weather disturbances, which are due to anti-monsoon conditions.

Mr. Blanford, in his admirable monograph on the rainfall of India, has compared the direct solar action which sets the monsoon in action to the pull of the trigger, by which the intrinsic latent energy of the resulting air-stream is shot forth. In the case of the chota barsât the comparison holds equally good only the resulting charge is feebler.

Now it has been recently maintained that while the distribution of temperature anomalies in the Indian peninsula regulates the inception of the little monsoon and its accompanying chota barsât, it is only when the central Asian plateaux become warmed up so as to produce an inflow beyond the Himalayan barrier, which must consequently affect the upper as well as the lower atmospheric strata, that any general deep movement of the equatorial vapour-laden air occurs on a scale sufficient to produce general monsoon rains. That in fact there are two movements, one in the lower air, and the other in the air above the first 5000 or 6000 feet, and that it is only when the two occur coincidently that we get the grander phenomena which accompany the burst of the big monsoon, as they term it in Ceylon. Some such theory appears necessary to account, not merely for the peculiar suddenness of the burst, but also for its variable date of arrival in different years. Until, however, we know more of the meteorological conditions of Central Asia and Thibet, this hypothesis must remain in a tentative state. Meanwhile, however, it is undoubtedly valuable to find that these two periods of rain-burst are not only distinct enough to be referred to under separate names over a large part of India, but in Ceylon are considered so important as to have their dates separately recorded by the Marine Master attendant at Colombo. In the excellent Ceylon *Mercantile and Planting Directory*, edited by the late Mr. A. M. Ferguson, and now carried on by his successor, Mr. J. Ferguson, a list is given of the dates of commencement of the little and big monsoons, from 1853 down o 1892 inclusive.

As a general result it is found that the average dates for the little and big monsoons are April 20 and May 19, and that when nothing particularly abnormal occurs, the big monsoon may be expected to follow the little one in about a month.

There are, however, considerable variations from this normal, the little monsoon date ranging through 52 days, and the big monsoon from May 1 to June 19.

On looking over these variations it struck me that they would probably be found to correspond to some extent with the rainfall of adjacent localities in India, especially the Carnatic. The result of a comparison of the anomalies is shown below—

	CEYLON.[1] Date of arrival of the big monsoon, before or after its average date, May 20. + Before – after days.	CARNATIC.[2] Mean rainfall anomaly in inches (40 stations). Inches.
1864	+ 5	– 5
1865	– 11	– 5
1866	– 2	– 4
1867	– 30	– 9·4
1868	– 14	– 4·6
1869	– 28	– 0·3
1870	+ 9	+ 1·8
1871	+ 7	+ 5·5
1872	+ 18	+ 11·5
1873	– 4	– 0·1
1874	+ 15	+ 7·3
1875	– 8	– 5·2
1876	– 17	– 13·2
1877	+ 4	+ 8·3
1878	+ 1	0
1879	0	+ 2·3
1880	+ 5	+ 7·0
1881	– 9	– 2·1
1882	0	+ 4·4
1883	+ 10	+ 5·2
1884	+ 5	+ 11·6
1885	– 16	– 1·1

A mere glance at these figures shows at once a remarkable parallelism both in signs and numbers. Thus in eighteen years the signs are alike, neutral in three, and unlike only once. As it is well known that the rainfall of the Carnatic was found by Mr. Blanford to vary in a cycle of eleven years, closely corresponding with that of the sunspots,[3] the same ought to hold for the anomalies in the dates of arrival of the big monsoon at Colombo. As a matter of fact the relation appears to be still

[1] From the Ceylon Directory, 1892.
[2] From the Rainfall of India, Part II., Indian Meteorological Memoirs, 1887.
[3] Mr. Blanford computed the probability of such a cycle as compared to an invariable average to be as 655 : 1. Indian Meteorological Memoirs, vol. iii. part 2, p. 244.

stronger. Thus, excluding insignificant decimals from the sunspot figures, and taking the mean of three and a half cycles for the Ceylon dates from 1854 to 1891, and from 1864 to 1885 for the sunspots in pairs of years from Wolf's tables (the only sunspot data I have available) we get the following comparison :—

		Ceylon[1] monsoon dates. Mean abnormals.	Sunspots. Mean abnormals.
1856	1867–'78	− 7·5 min.	−38 min.
1857	,,	− 3·2 ,,	−34 ,,
1858	,,	− 1·0 ,,	−15 ,,
1859	,,	− 4·0 ,,	+27 ,,
1860	,,	+ 2·0 ,,	+44 max.
1861	,,	+10·0 max.	+37 ,,
1862	,,	+ 4·0 ,,	+26 ,,
1863	,,	+ 3·0 ,,	+ 9 ,,
1864	,,	+ 1·0 ,,	− 9 ,,
1865	,,	− 4·0 ,,	−21 ,,
1866	,,	± 0·0 ,,	−30 ,,

Better sunspot data would certainly not invalidate the connection. The lag behind the maximum sunspot data and the apparent tendency to precede the minimum has always been noticed in other phenomena. Moreover, from the analogy between the abnormals of the two elements compared both in quantity as well as sign the same remarks as to the reality of the cycle made by Mr. Blanford in his work (cited ante) p. 254 apply *pari passu* to that in the Ceylon dates.

A similar relation holds good for the little monsoon which may be put into words as early dates in years with increasing sunspot numbers and late dates in years with diminishing sunspot numbers, with a decided maximum of twelve days early in the year immediately succeeding that of maximum sunspots. Even the period between the two bursts shows symptoms of a similar relation to the sun's condition, the mean maximum interval, forty-three days, corresponding to the year of minimum sunspots, and the minimum twenty days occurring two years after that of maximum sunspots. The relation, however, is clearest in the figures for the burst of the big monsoon and seems to show that apart from all indirect influences such as accumulation of snows on the Himalayan outer ranges, and unusual winter rainfall on the plains or the reverse, there is a real fluctuation in the dates of the burst of the big monsoon or burra barsât connected with the sun's condition which appears to be more direct than that exhibited by the amount of rain which falls during its continuance and appears to indicate, as indeed is borne out by what we know from other sources, that in years of many spots the conditions which usher in the summer monsoon rains are earlier developed, and, as the amounts show, probably continue more regularly than in years of few spots.

Granting this as a working hypothesis two important results follow.

(1) The parallel march of the Ceylon dates and the rainfall of the Carnatic shows that the former could be employed to forecast the probable amount of monsoon rainfall about to be enjoyed in the latter district.

(2) That by using the mean abnormal of the year in its position in the sunspot cycle as the true mean instead of the mean of the whole period, the true abnormal for the year can be better estimated and the probable general character of the weather foretold.

As an example let us take the well-known diurnal variation of barometric pressure, whose amplitude in the tropics is so large that it bears a sensible ratio to the abnormal fluctuation produced by a passing disturbance.

In estimating the true abnormal at some particular hour of the day we must evidently compare the value with reference to the normal *at that hour*.

Similarly for the sunspot period in the case under consideration. If there is reason to believe that the period exists we ought to treat it as a reality, and in constructing graphic abnormals take the curve of the progressive cyclic normal as our abscissa axis instead of a straight line representing an endless repetition of the mean of the whole period. The principle is adopted as regards varying locality in drawing synoptic abnormal charts. It should be equally imperative in cases where the element of time is considered.

Thus in 1894, if the monsoon burst in Colombo twelve days before its time it would be abnormal to the extent of +2. On the other hand, if it were twelve days late, it would be abnormal to the existing mean to the extent of −22, and even to the new mean formed by incorporating this fresh value, to the extent of −16, and we might in such a case infer that some unusual cause was in operation which would certainly bode ill for the Madras agriculturists.

I have put these facts and considerations forward simply as a preliminary inspection of two phenomena which not only occur in Ceylon, but are more or less common to the Indian peninsula, and to show how conditions, the relations between which can at present only be exhibited in an empirical form, may yet be employed as a means of forecasting the character of a season, and also ultimately by further investigation help to elucidate the whole machinery by which the grand weather changes are produced by terrestrial physical conditions in conjunction with alterations in the state of the sun's surface as well as its varying declination. A large field on either side of the equator, embracing one-fourth of the entire area of the world, exists, from which observations are very much wanted to complete our knowledge of the causes of phenomena which, while they are evidently closely related to action-centres (using Teisserenc de Bort's significant expression) at some distance from the equator, are yet, probably to some considerable extent, dependent upon conditions prevailing over the entire equatorial belt, which may, for all we know, fluctuate in stricter unison with solar changes than those which occur in higher latitudes.

E. DOUGLAS ARCHIBALD.

[1] These figures are simple means *unsmoothed*.

Singular Swarms of Flies.

WITH the writer's permission I send you herewith a letter which I have received concerning the subject of my letter which appeared in your issue of June 1.

During the week following the date of my letter I repeatedly saw swarms of similar kind; but smaller and less marked, seldom visible much more than fifty yards away; always under similar atmospheric conditions, which were chronic during the period in question. The swarms always showed much the same slant from vertical (some 30° or so), the direction of the slope in plan being towards such slight draft of air as was perceptible.

R. E. FROUDE.

Gosport, June 12.

I FIND in NATURE, June 1, an inquiry you make about flies forming clouds, resembling smoke.

They are usually produced by the gnats called scientifically *Chironomus*, and have been often mentioned in entomological literature.

I give below several references I can lay my hand on, but there are probably many more recent ones, which I have not noticed—

German, Magazin für Entomologie (in German), vol. i. p. 134–140, 1813.

Clapton, J. C. Dale, in Magaz. Nat. Hist., 1833, p. 544. (In Ireland and England.)

Patterson, Ann. and Mag. of Nat. Hist., vol. x. 1842, p. 6–9.

I have seen such clouds myself more than once. Cases have occurred when the smoke-like appearance has caused a fire alarm to be sounded.

C. R. OSTEN SACKEN.

Heidelberg, Germany, June 4.

OFFICIAL CATALOGUE OF THE EXHIBITION OF THE GERMAN EMPIRE AT THE COLUMBIAN UNIVERSAL EXHIBITION IN CHICAGO.

GERMANY, not unmindful that America is her best customer, will be worthily represented at Chicago. An elaborate catalogue, in the German language, has already appeared, and an English translation will shortly be published. We have been favoured with an advance copy of the latter, which is by no means a mere enumeration of exhibits. It contains a general introduction, and a number of original articles by leading experts, "intended to supply for each department a concisely descriptive survey of its development and present condition." There is also, in German and English, a special Guide to the collective exhibition of the German chemical industry, containing historical and statistical notices of every exhibiting firm. Generally the effort of the editor, and the commission which he represents, has been to convey to the American people and to the world a faithful picture of a state of development of the industrial arts in Germany, which may well inspire,in the English reader, impressions of a mixed order, pleasure in the contemplation of a great national growth, based upon a true conception of the right methods, and regret that in our own country a similiar consummation still appears a great way off. The selection, as editor of this publication, of the eminent chemist, Dr. Otto N. Witt, professor of technology at the great Berlin Polytechnicum, is in itself a forecast of its scope and purpose, and an evidence of the position which the man of pure science occupies in official Germany. To summarise in the briefest manner the work which he and his collaborators have given to the world would carry us far beyond the limits of this article. There are two points, however, of paramount interest, to which we desire to call attention, the one social-political, not to say socialistic, the other industrial—both of national importance.

Among the provisions made and establishments created by the newly-founded empire avowedly in the interest of national industry and commerce, such as the Imperial Post Office, the Imperial Bank, the Imperial Patent Office, none bear the stamp of originality in the same degree as the great system of compulsory insurance, "the object being to secure for that portion of the population which is dependent upon the work of its hands, and is rarely in a position to save money or properly to administer its savings, a provision for the days when through accident, sickness, or advancing age the worker is incapacitated from further earnings. Insurance is applicable in three different forms. In assurance against illness, introduced in 1883, the means are provided, two-thirds by the insured and one-third by their employers, in weekly contributions, to an amount not exceeeding 3 per cent. of the average wage. It entitles the insured to free medical treatment and a fixed allowance over a given period. It includes 7,000,000 persons in more than 20,000 clubs, and involves an annual expenditure of more than 100 million marks. The system of insurance against accident, which came into existence in 1884, is intended *to transform the personal liability of the employer, in case of accident during the execution of work into an economical charge upon the entire trade concerned*, to secure to the worker an indemnity *in all cases*, and to put an end to troublesome lawsuits between employer and employed. At the present time 15 millions of persons are insured, and 10 millions of marks have been paid in indemnities. The insurance against incapacity for work, and the old-age pension fund, inaugurated in 1891, complete this system of workers' insurances. It insures an income to those unable to earn a living, without reference to age, and an old-age pension to septuagenarians, without reference to any capacity for earning which they may still retain. The necessary means, in addition to a yearly Imperial contribution of 50 marks per income, are supplied in equal proportions by the insured and their employers. This form of insurance includes 12 millions of persons, and has, up to the present time, involved an outlay of 30 millions of marks. On the whole, there has been, in connection with the objects of the operatives' insurance, an expenditure of well-nigh half a milliard of marks, which has exclusively benefited the working-classes."

Thus, in the course of eight years, the German Government and people have given practical form to these grave social problems, which, in our own country, are still waiting for solution. Whether the German system is based on sound principles it is not for the present writer to decide. It is admitted that it imposes a heavy burden upon industry, and yet most of the exhibiting firms appear to bear it with equanimity. Nay, it is refreshing to note that the obligations imposed upon manufacturers by the Legislature have not in any way dried up the springs of voluntary charitable effort. Most of the large firms, in addition to the requirements of the law, make generous provision for their workpeople in the shape of baths, refreshment-rooms, dormitories, supplies of fuel at cost price, model cottages at low rent, allotments, and various funds in cases of sickness and death, funds for widows and orphans, &c., &c. It must be borne in mind, as a set-off to all this benevolence, that wages are low. The average remuneration in chemical factories, for example, is something less than £1 per week for a ten hours day.

The other point suggested by a perusal of the catalogue is the rapid and, in some cases, triumphant progress of German industry. For our present purpose it will be sufficient to consider two departments of chemical manufacture—namely, the industry of general and fine chemicals and that of artificial colouring matters. They are typical of the spirit which pervades every branch of technical activity in Germany. The former, we are told, has developed to an extent unknown in any other country in the world. Imperial statistics show that in 1891 there were in Germany 521 factories engaged in the manufacture of chemico-pharmaceutical preparations, their 14,842 workpeople drawing 12,615,700 marks in wages. The exports in 1890 of chemical preparations, not specially named, exceeded the imports by 5000 tons, valued at more than 15,000,000 marks. If to these are added the chemicals quoted by name in the official list, we obtain a total excess of exports over imports amounting to 25,690,000 marks; and as the home consumption must at least be equal, we arrive at a grand total of 52,000,000 marks annually.

More remarkable still is the history of the great dye industry, which, as is well known, originated in England with the labours of Hofmann, Mansfield, and Perkin, closely followed in France by those of Verguin and Girard and de Laire. What has become of it? The chemical catalogue tells us that nine-tenths of the production of artificial dye-stuffs in the world must be credited to Germany.

There are altogether some 20 factories belonging to this industry in Germany, nearly all of which can claim to be important. Three of the largest are represented at Chicago. One of them, with a capital of 6,000,000 marks, employs 600 men and 90 women; another, with a capital of 12,000,000 marks, occupies 1600 men with a technical staff of 300, and produces nearly every known dye stuff, the alizarine dyes included. A third, with a capital of 16½ million marks, is said to be the largest chemical factory in the world. It began twenty-eight years ago with a staff of 30 men, and now employs 4000. These three factories have played a conspicuous part in the building up of the industry of artificial colouring matters.

To what causes must these great results be traced? Many minor causes are mentioned in the catalogue. Let us, however, go at once to the root of the matter. The two main factors are organisation and the consequent intimate connection between pure science and manufacture. When, at the beginning of the century, Germany lay crushed at the feet of Napoleon, it was felt by German patriots that nothing but the complete re-organisation of the country could lead to its emancipation. Since those days, side by side with the military forces, the scientific forces of the country have been carefully and patiently organised. At the instigation of Liebig, great State laboratories for pure scientific research were erected all over the country, and from these have issued an army of highly-trained workers, whose services manufacturers have vied with each other in securing. Nothing is more striking, in the special notices of the exhibiting firms, than the large number of competent and often distinguished chemists employed in all the factories at all connected with the chemical trade.

Firms with 40 workmen sometimes employ as many as 5 or 6 chemists, and the three great colour firms referred to above employ together 178. In the words of Dr. Witt: "In chemical research the chemical industry of Germany possesses a never-failing helpmeet, and such is the intimacy between chemical research and chemical manufacture, that the periods of most rapid development of the one have always been epochs of prosperity with the other." And again: "It may be asserted that not only is the strength and productive power of German chemical industry based upon the intimate connection between science and practice above described, but that in that intimacy lies the surest safeguard that German industry will long continue to hold the prominent position which, with such strenuous exertion, it has ultimately achieved. When the question is asked why the chemical industry of other lands, still more favoured perhaps by nature, has in the end been surpassed by the German, the answer is that Germany has had the good fortune to call her own a number of the greatest intellects in the domain of pure scientific research, who have quickened the pace of theoretical chemistry. But, as before stated, it is the latter which constitutes the vital element of chemical manufacture. Only the country which, at any period, shall assume the leadership in pure scientific chemical investigation, will also be in a position to wrest from German chemical industry the palm to which it is at present entitled."

We do not shut our eyes to the fact that nations, like individuals, must work out their own character and destiny, nor do we for a moment inculcate a slavish copying of the German model. We have in this country a great deal of science and a great deal of industry, and many attempts have been made to bring about an effective cooperation of these two cardinal elements of productive energy. We cordially recognise that particular industries and individual firms have, by private ent:rprise, developed themselves upon a thoroughly scientific basis, and we also welcome the fact that substantial additions have been made in recent years to the laboratories and institutions where a scientific training can be obtained. At the same time we cannot escape from the admission that, in the friendly struggle for industrial supremacy, Germany has not only made astonishing progress both in the development of industries of long standing, and in the inception of new ones of enormous fruitfulness, but that she has been the first as a nation to solve the great problem of the cooperation of science and manufacture. We leave it to more competent hands to point out the course which now lies before us. In our own humble opinion the days of *laisser faire* have gone never to return, and the time has come when the Government of the country, backed by the country, must take—as is the case in Germany—a larger share than it has done hitherto in the systematic organisation of our scientific and industrial forces. A nobler and a more patriotic task could hardly be attempted.

THE REDE LECTURE.

At Cambridge, on June 14, the Rede lecture was delivered by Prof. Michael Foster, Sec. R.S., his subject being "Weariness." The lecture was illustrated by experiments, conducted by Dr. Shore, with the assistance of Mr. Hardy. The following report of the lecture is from the *Times*:—

Prof. Foster said that among the many shortcomings which limited the power, and so the usefulness, of the machine which we call the human body, two stood out prominent among the rest: these were, on the one hand, inertia or laziness, the unwillingness to stir, and, on the other hand, weariness, the getting tired. He proposed to lay before his audience some account of such knowledge as the physiologists of to-day possessed, and it was but little, concerning the physical basis of this weariness, which so greatly shortened the power of man. He began with a simple yet illustrative case—the weariness which comes from the much repetition of a simple movement, a simple muscular act, as when a man lifts a weight with his hand. Analysing the act physiologically, he showed the changes which took place in the brain, the nerve, and the muscle. Taking the muscle first, he showed that weariness of muscle comes, in the first place, from too rapid expenditure of capital; secondly, from the accumulation in the muscle of the products of the muscle's own activity. There were many reasons for thinking that this latter cause of weariness was at least as potent as the former. The brute force of our food was the measure of our muscular strength, but the one could become the other only through the aid of many other things which might be wholly empty of energy, and the failure of these, no less than the absence of the former, entailed at first premature weariness, afterwards failure and death. The nerves and the brain shared in even the simplest and rudest muscular work. The nerves themselves, the mere bundles of fibres which carried the nervous impulses from the brain to the muscles, were never tired. Coming to the brain, the lecturer showed by a simple experiment a case of fatigue, demonstrating that the fatigue was in the brain and not in the muscle; a weariness of the particular part of the nervous system which was called into play.

By an illustration in colours he showed also how weariness not only lessened work but bred error. The study of the central nervous system had led, and was leading, physiologists to the conclusion that the material changes on which its activity depended were very analogous to those taking place in a muscle, only, of course, from a chemical point of view, not so massive. And all they knew went to show that in the brain, as in muscle, weariness was the result on the one hand of an expenditure of capital disproportionate to the accumulation, and on the other hand to a clogging of the machinery with the products of activity. The simple apparatus he had used might be successfully employed to illustrate general conditions as affecting weariness. If, taking always the same weight, they counted the number of times the weight was lifted and measured the height to which it was raised each time in succession before the movement was stopped by weariness, they could ascertain how much work had been done before the machine was so stopped. Proceeding in this way some interesting results as to what hastened or retarded fatigue had been obtained. Practice and habit, it was needless to say, were of prime influence. The depressing effects of a damp, muggy day, or the exhilarating effects of a bright, clear day, might in this way be measured in foot-pounds of power lost or gained, as might also the lowering influence of a cigar and the heightening effect of a glass of beer. One point perhaps he might dwell upon, and that was the influence of that part of the brain which was more immediately concerned with what was spoken of as mental work. An Italian professor determined, by means of the apparatus of which they were speaking, the amount of work which he could on a certain morning do before he was stopped by weariness. He then set himself to two hours' hard mental work, and the form of work he chose was that of examining candidates for their degree. The professor, as soon as the two hours' examination was over, went back to his apparatus and found that his power of bending his finger was enormously cut down. The nervous system was a candle which could not profitably be burnt at two ends at once. When the work done involved the activity, simultaneous or successive, of many muscles of many parts of the nervous system, the several efforts by accumulation became prominent, and simple weariness passes into what was called "distress." Here the result depended not so much on the direct effects of the work on the parts which were actively employed, not so much on the changes wrought in the muscles or in the nervous machinery at work, as on the success with which other members of the body came to the aid of those actually engaged in labour. The internal life of the body, no less than the external life, was a struggle for existence, a struggle between the several members, a struggle the arena of which was the blood. And it would seem that the onset of distress was chiefly determined by the failure of the organs to keep the blood adequately pure. Something depended on the vigour of the muscles themselves, something on the breathing power of the individual, something also on the readiness with which the heart responded to the greater strain upon it; but beyond and above all these was the readiness with which the internal scavengers freed the blood from the poison which the muscles were pouring into it. Undue exertion was exertion in which the muscles worked too fast for the rest of the body. The hunted hare died not because he was choked for want of breath, not because his heart stood still, its store of energy having given out, but because a poisoned blood poisoned his brain and his whole body. So also the schoolboy, urged by pride to go on running beyond the earlier symptoms of distress, struggled on until the heaped up poison deadened his brain, and he fell dazed and giddy, as in a fit, rising again, it might be, and stumbling on unconscious, or half conscious only, by mere mechanical inertia of his nervous system, falling once more, poisoned by poisons of his own making. All our knowledge went to show that the work of the brain, like the work of the muscles, was accompanied by chemical change, and that the chemical changes were of the same order in the brain as in the muscle. If an adequate stream of pure blood were necessary for the life of the muscle, equally true, perhaps even more true, was this of the brain. Moreover, the struggle for existence had brought to the front a brain ever ready to outrun its more humble helpmates, and even in the best-regulated economy the period of most effective work between the moment when all the complex machinery has been got into working order and the moment when weariness began to tell was bounded by all too narrow limits. If there were any truth in what he had laid before them, the sound way to extend those limits was not so much to render the brain more agile as to encourage the humbler helpmates, so that their more efficient cooperation might defer the onset of weariness.

NOTES.

FROM the *Times* we learn that a volcanic outbreak has occurred at Fukushima, in Northern Japan. Large volumes of dust and vapour have been emitted, and the country for miles around has been covered with volcanic ash. Landslips of great extent have occurred in the same neighbourhood, and are supposed to be caused by the volcanic action.

DR. H. J. JOHNSTON-LAVIS sends us the following information:—After many years in which the crater of Etna has been in a solfataric state lava has again risen, and now occupies it. This is a very rare condition of things in that volcano. Earthquakes continue in the north of Sicily, but on the flanks of Etna there is marked quiescence, which might be expected when the main chimney is free.

ON June 13 a select committee of the House of Commons resumed the hearing of evidence in connection with sea fisheries. Prof. Ray Lankester urged that a proper survey should be instituted round the coasts, in order to ascertain the movements and habits of fish in the areas resorted to by fishermen. An adequate commercial return could be expected from such a survey, for new fishing grounds might be discovered. To carry on this work, the present Government Grant of £1000 a year, received by the Marine Biological Association, ought to be trebled, and a grant of £5000 should be made for a deep-sea vessel. Dr. Günther expressed the opinion that hatcheries should be established for the protection and extended cultivation of sea-fish, and Mr. Holt testified to the considerable depletion of the fisheries in the North Sea, to prevent which a size-limit for different kinds of fish was recommended, rather than an absolute close-time of four months in the year.

A PHOTOGRAPHIC exhibition usually includes mechanical appliances and improved outfits specially designed to catch the eye of the artless amateur photographer. But there is to be a new departure in this, as in many other customs. In October next an exhibition of photographic pictures, to be called the "Photographic Salon," will be held at the Dudley Gallery, Piccadilly, and it will be concerned, wholly and solely, with photographs of pictorial merit, leaving the means by which such results can be obtained to be otherwise advertised. Those who desire to have their pictures hung in this academy of photographic art should communicate with the secretary before the beginning of September.

A NUMBER of lectures will be delivered in connection with the Gilchrist Trust, from September to December, in the Great Assembly Hall, Bethnal Green. Prof. V. B. Lewes will open the series with a lecture on "The Atmosphere and its Relation to Life." He will be followed by Sir Robert Ball, on "Other Worlds," Dr. Andrew Wilson on "The Brain and Nerves," the Rev. Dr. Dallinger on "Spiders: their Work and their Wisdom," and Dr. J. A. Fleming on "Magnets and Electric Currents."

LOVERS of the piscatorial art will welcome the suggestion that the 300th anniversary of the birth of Izaak Walton, on August 9, shall be commemorated by some memorial. There is a marble bust of Walton at his birthplace, Stafford, and a statue at Winchester, where he is buried, but in London, the home of his adoption, his claim to have his name and work written on a memorial tablet has hitherto been neglected. Mr. Marston, of the *Fishing Gazette*, thinks St. Dunstan's Church, Fleet Street, would be an appropriate building whereon to affix a mural decoration. In commemoration of the tercentenary, a special edition of "The Complete Angler" will be published by Messrs. Bagster in September. Mr. J. E. Harting, librarian to the Linnean Society, is editing the volume, and adding to it notes from the point of view of a naturalist.

AN international anthropometrical congress will be held at Chicago, from August 28 to September 2, under the auspices of the World's Congress Auxiliary of the Columbian Exposition. It is requested that the titles and abstracts of papers on anthropology be forwarded as early as possible to Prof. C. Staniland Wake, Department of Ethnology, in order that the programme may be arranged.

MR. A. O. WALKER informs us that about 8.15 p.m. on June 15, three shocks in rapid succession were felt at Colwyn Bay. The shocks present the characteristic features of true earthquakes, but evidence from a wider area is required to decide the question.

THE thunderstorms which occurred in some parts of our islands about the middle of last week were accompanied generally by very little rain; in parts of Kent, for instance, the total rainfall since the beginning of March has only amounted to about three-quarters of an inch, or 13 per cent. of the normal amount. The temperatures have been exceptionally high, the maxima ranging from 80° to 88° in many parts of the kingdom, while on Monday the 19th instant, the temperature reached 91° at Greenwich. This is the highest reading which has occurred there in June since the year 1858, and it has not been exceeded in any part of the summer during the last five years. In the early part of the present week shallow depressions passed over these islands causing the recurrence of thunderstorms in many parts. These were accompanied by smart showers in a few places, and by a considerable fall in the temperature, the maximum in London on Tuesday being 24° lower than on the previous day. The *Weekly Weather Report* of the 17th inst. showed that the mean excess of temperature ranged from 3° or 4° in England, to 6° in Scotland, and to 7° in the north of Ireland. There was no rainfall whatever over the greater part of England and Scotland.

The Vatican Observatory has issued the third volume of its *Pubblicazioni*, containing xxiii + 442 quarto pages and thirty plates. The plan followed by Padre Denza is the same as in the previous volumes, and the work is produced in the same excellent style. After quoting some historical documents relating to the observatory, an account is given of the last general meeting of the superintending Council and of the principal astronomical and astrographic researches carried on at the observatory. Although the magnetical and geodynamical sections are not yet in order, several papers of special interest in these important subjects are published. The meteorological section contains hourly observations and results for the year 1891; in this branch we specially notice a paper on the classification of clouds by Sr. F. Mannucci, photographic assistant at the observatory, illustrated by fourteen photographs taken at the observatory and neatly printed by Dujardin of Paris. The classification adopted is that proposed by Messrs. Abercromby and Hildebrandsson, and consists of ten different kinds of clouds, divided into five principal groups, according to the heights at which the various forms are usually found. The last part of the work contains an account of the proceedings of the ordinary meetings held in the year 1892.

Probably few people are aware that there still exists in this country a manufactory of gun and tinder-box flints, yet such is the case. Mr. Edward Lovett, in the *Illustrated Archæologist* for June, gives an interesting description of the flint industry which has been carried on at Brandon, situated on the borders of Suffolk and Norfolk, since the Stone Age. The methods employed in the mining and fashioning of flints at that remote period prevail, with little alteration, unto this day. In order to break flint into pieces of convenient size, the worker places the mass on his knee, and, by a dexterous blow with a hammer, shivers it into fragments as easily as if it were chocolate. The pieces are then split into flakes, and these, in turn, are fractured into little squares which, with very slight trimming, become the finished gun-flints. Most of the gun-flints are exported to Zanzibar and other ports in communication with the interior of Africa, but, besides these, large quantities of flints for tinder-boxes are still made at Brandon. Tinder-box flints chiefly go to Spain and Italy for use in isolated districts. It is a curious fact, however, that the flint-and-steel method employed by prehistoric man in making fire is better than matches in uncivilised regions, and very moist climates.

At a recent meeting of the Société Française de Physique a note from Dr. Stephane Leduc was read, in which the correspondant points out that the physiological effects of alternating currents obtained from electrostatic machines are very different to those up to now observed with ordinary alternating currents of high tension and frequency. Thus, if the terminals are held in the hands nothing is felt, although a continuous stream of sparks is passing between the dischargers. If, however, the current is localised at one point on the skin by means of a rounded point, directly this point passes over a nerve, either sensory or motor, the nerve is excited throughout all its length beyond the electrode. The sensation felt in the sensory nerves allows of their distribution being accurately followed, while the least displacement of the electrode on the surface of the skin causes a cessation of all these effects. These currents can in this way be used to localise the seat of nervous excitation with much greater accuracy than has been hitherto possible.

The results obtained by Blondlot in his extensive research on the capacity of polarisation have been confirmed by some recent experiments of M. Bouty (see Proceedings of the Société Française de Physique). M. Bouty has chiefly studied the case of melted electrolytes, of extremely dilute solutions of salts and of solid electrolytes, and his results have very conclusively shown that the initial capacity of polarisation (K) is independent of the direction of the polarising current. When a platinum electrode has been immersed in a melted electrolyte for twenty-four hours it possesses, for a given temperature, a constant initial capacity of polarisation, which increases rapidly with temperature, while the maximum polarisation decreases. In the case of electrodes of platinum in concentrated solutions of most salts (those of platinum excepted) the value of K is very nearly the same for all, and varies little on account of dilution, while there appears to be no connection between the value of K and the specific resistance of the solution.

A curious optical illusion is described by M. Bourdon in the *Revue Philosophique*. If an object moves before our eye, kept fixed, it undergoes, in passing from direct to indirect vision, an obscuration, a change of coloration; and the opposite effect occurs when the object comes into the field of direct vision. It is natural to suppose that this plays a part in the perception of motion, and one fact proving that it does so is, that if we render a slow-moving object suddenly invisible, *e.g.* by means of a shadow, its velocity of displacement seems much increased. M. Bourdon describes an arrangement in which a long pendulum with white thread is swung from a cross bar on a vertical support, which is illuminated from a lamp, while a screen is introduced to give a shadow (the order being, observer, lamp, screen, vertical support, pendulum, dark wall). The white thread in its swing passes into the shadow of the rod and screen, and each time it enters or reappears its velocity seems increased considerably. It seems as if attracted into the shadow, and as if it entered into the light with a sudden shock. It is necessary that the thread should cease to be visible when it enters the shadow. With a red thread the illusion also occurs, perhaps somewhat less vividly. A simpler plan than the above is to hang a pendulum from the ceiling, shading with a screen.

A new method of determining the hardness, or rather perhaps the friability of substances, has been described by Hr. August Rosiwal at a meeting of the Vienna Academy. The measurements consist in comparing the losses of weight sustained by the bodies under investigation by scratching them with a given weight of polishing material mounted on a metallic or glass base until the material loses its efficiency. The polishing materials used were dolomitic sand, emery, and pure corundum. The diamond was assigned its place in the scale of hardness by comparing its efficiency as a polishing material with that of corundum. It was found to be 140 times as hard as corundum. Tested by this method, the constituents of Mohs's scale have the following numerical values:—Diamond 140,000, corundum 1000, topaz 194, quartz 175, adularia 59·2, apatite 8·0, fluorspar 6·4, calcite 5·6, rocksalt 2·0, and talc 0·04. The great advantage of the method consists in the ease with which the hardness of mixtures of minerals in the various rocks is determined.

PROF. OBERBECK, of Greifswald, has been studying the spreading of oil on liquid surfaces on a larger scale than that of ordinary laboratory work. The experiments, which are described in the current number of *Wiedemann's Annalen*, were carried out in the Bay of Rügen, upon which the Prussian university town is situated. The professor sailed out into the bay for a distance of 2 km. or so, accompanied by an experienced mariner, and armed with bottles holding from one-tenth to half a litre of machine oil or rape-seed oil in measured quantities. Sitting in the stern of the vessel, he poured the contents of the bottles at intervals into the water in a thin continuous stream, the vessel meanwhile moving at a uniform rate in the same direction. After about an hour the oiled tracks were revisited. The brilliant colouring had disappeared, and the oil had spread out into well defined rectangular light-grey patches, easily distinguished from the rest of the sea by the absence of ripples and their consequent superior reflecting power. Their area was estimated, with the aid of the experienced mariner, by the time occupied in sailing past. In the case of the half-litre bottle the patch measured 300 by 30 metres, thus giving an area of 18,000 square metres corresponding to one litre of oil. A more accurate measurement was made subsequently by means of a line of buoys marking the deep-water channel. This gave an area of 18,857 square metres. Hence the thickness of the film of oil was 53 millionths of a mm. It is, of course, possible that the oil had spread still further and had only ceased to influence the ripples on the surface. In that case the film must have been even thinner.

THE applications of electricity to every-day life seem to be almost infinite; the latest development being an electrical horsewhip described in *Électricité*. This is said to be designed for the use of a "sportsman," and consists of a celluloid handle containing a small induction coil, together with a battery, the circuit being closed by means of a spring push. Two wires carry the current to the extremity of the whip, which is furnished with two small copper plates having points fixed to them of sufficient length to penetrate the coat of the horse, and yet not being sharp enough to inflict a wound.

IN a note contributed to the Accademia dei Lincei, Augusto Righi gives a short description of a form of apparatus he has used for producing Hertzian oscillations of short wave-length and exhibiting their properties to an audience. The oscillator consists of two rods furnished with balls at either end and placed between the discharger of a Holtz machine, leaving a gap of about 4 centimetres at each end, and one of about 3 mm. at the middle. The two rods pass through the sides of a glass vessel containing oil, so that the middle pair of knobs are surrounded by oil. The resonator consists of a nearly complete circle of wire, the gap being filled by a Geissler tube. With the above apparatus the author has carried on a series of experiments on the reflection, refraction, and interference of these electrical waves.

AN abstract of a paper by C. H. Morse appears in the *Electrician*, giving an account of the damage to the water-pipes in Cambridge (Mass.), caused by the electrolytic action of the return current from the electric cars. Pipes composed of lead, iron, galvanised iron, brass, and rustless iron were in turn tried and found to deteriorate quickly. Such an amount of current was found to be flowing along the pipes that, upon attempting to make a joint by putting oakum round the pipe, an electric arc was formed and set the oakum on fire. The damage has to a great extent been checked by connecting the gas and water-pipes together, and also to the negative pole of the dynamos which supply the power to the railway.

AT the beginning of this year (says the *Revue Scientifique*, June 17) there were 1168 submarine cables in existence, of which 880 belonged to different dominions and 288 to private companies. The former possessed a length of 16,652 miles, and the latter had a length of 144,743 miles, thus the total length was 161,395 miles. Fifty-four of these cables belong to the state in France, the length being 3979 miles; and Germany owns 46 cables, having a total length of 2025 miles. There are 14 Anglo-French cables, 10 Anglo-Belgian, 8 Anglo-Dutch, and 13 Anglo-German. Of the cables possessed by private companies the Eastern Extension, Australasia, and China Telegraph Co. head the list with 25 cables and a mileage of 18,205; the Great Northern Telegraph Co. follow with 24 cables, having a total length of 6948 miles; then come the West India and Panama Telegraph Co. with 22 cables extending through 5240 miles: and the Western and Brazilian Telegraph Co. with 15 cables stretching over 5408 miles. The French Society of Submarine Telegraphs possess 14 cables having a total length of 3754 miles.

THE "shell-beds," or shelly clays, in the north of Scotland—at Clavia near Inverness, and on the east coast of Aberdeenshire, have been investigated by Mr. Dugald Bell, and the results of his researches were communicated to the Glasgow Geological Society on May 25, under the title "The alleged proofs of submergence in Britain, during the Glacial Epoch." Mr. Bell holds that it is doubtful if this clay were really in place, as part of an ancient sea-bottom, during the glacial epoch. He thinks also that the "red clay" of East Aberdeenshire, described by Mr. Jamieson, cannot be accepted as a satisfactory proof of submergence, indeed, in some respects, its characteristics seem to be inconsistent with that theory.

FROM the *Pioneer Mail* we learn that Mrs. J. S. Mackay has a superb snow leopard at Kulu, in the Punjab. Though the animal is nearly full-grown, he is practically free and lies about the house all day like a huge cat, or romps with his mistress. His ultimate destination is the Zoological Gardens of London. Should he be brought over alive he will be the only animal of his kind in Europe.

IN a paper, "Sulla presenza di batteri patogeni nella saliva di alcuni animali domestici" (Fiocca: *Annali dell' Istituto d'Igiene Sperimentale della R. Università di Roma*), an examination of the saliva of numerous horses, dogs, and cats is recorded. The saliva of the horse was found to contain diverse bacilli, also streptococci, staphylococci, and one spirillum. Amongst these organisms three were discovered which possessed pathogenic properties; and one of these, a bacillus, was very frequently found, for out of fifteen different samples of saliva inoculated into guinea-pigs it was only once absent. This organism is distributed in soil, and it is very possibly also frequently present on grass and hay, and hence its prevalence in the saliva of horses. The saliva of the cat presented a very different appearance from that of the horse, being very rich in cocci and minute bacilli. A new bacillus (*Bacillus salivarius felis*), extremely characteristic of cats' saliva, was isolated and found to be specially pathogenic to rabbits and guinea-pigs, these animals dying from its effects in twenty-four hours. The dog's saliva was found to contain the largest variety of bacteria, amongst the pathogenic forms isolated being the *B. pseudo-œdematis maligni*, and the *Staphylococcus pyogenes aureus*.

SOME investigations on the antagonistic effect produced by the *Bacillus fluorescens liquefaciens* on other organisms have been made by Olitzky (*Ueber die antagonistischen Wirkungen des B. fluorescens liquefaciens und seine hygienische Bedeutung*, Bern, 1891). Cultures of this bacillus were either streaked on to nutritive agar-agar side by side with other organisms, or the latter were separately inoculated on to culture material in which this bacillus had grown, but which before being used for the second time was re-sterilised, the growth being thus destroyed, but the *products* remaining. It was found that the tubercle bacillus and the pneumococcus of Fraenkel were quite unaffected, whilst the *B. prodigiosus* only refused to grow in the re-sterilised culture material. On the other hand the *Staphylococcus pyogenes aureus*, the anthrax bacillus, and the typhoid bacillus were greatly impeded in their development, and no growths whatever made their appearance in the re-sterilised culture material. The cholera bacillus and the *B. pyocyaneus* were also affected, but to a smaller extent.

SHORTLY before his death, Mr. Darwin informed Sir J. D. Hooker, F.R.S., that "the difficulties he had experienced in accurately designating the many plants which he had studied, and ascertaining their native countries, had suggested to him the compilation of an 'Index to the Names and Authorities of all Known Flowering Plants and their Countries' as a work of supreme importance to students of systematic and geographical botany, and to horticulturists." "At his request," adds Sir J. D. Hooker, "I undertook to direct and supervise such a work." The Clarendon Press announces that Part I. of this "Index Kewensis" is now ready, that Part II. is well advanced, and that the completion of the whole work may be expected next year.

THE first part of Prof. A. Newton's "Dictionary of Birds" has just been published by Messrs. A. and C. Black. It extends from aasvogel to the gare-fowl, or great auk, and runs into 304 pages. The work is founded upon a series of articles contributed by Prof. Newton to the ninth edition of the "Encyclopædia Britannica." Important additions have been furnished by Dr. Hans Gadow, and for other contributions Mr. R. Lydekker, Prof. C. S. Roy (who has written an interesting article on "Flight"), and Dr. R. W. Shufeldt are responsible. A commendable feature is the inclusion of many names of birds, such as the *caracara*, *koel*, and *mollymawk*, which are frequently found in books of travel but are not explained in an ordinary dictionary. Compound names of the *crow-shrike* and *thrush-titmouse* kind have, however, been omitted.

MR. R. L. JACK, the Government Geologist of Queensland, has prepared a report on the Russell River Gold Field. The report is accompanied by a geological map of the district.

WE have received a dissertation by Mr. E. M. Blake, in which he discusses the application of the method of indeterminate coefficients and exponents to the formal determination of those integrals, of certain systems of differential equations, which are expressible as series.

THE Harvard University Bulletin for May is a long list of accessions to the University Library. This list includes, in addition to recently-published books and pamphlets, a number of extensive and important works of earlier date. Nearly one hundred and fifty books in the list are concerned with science and the arts.

MESSRS. MACMILLAN AND CO. have published a second edition of "Lessons in Elementary Biology," by Prof. T. Jeffery Parker. The whole of the book has been thoroughly revised, and two of the lessons have been largely rewritten. A number of new figures have also been added.

MR. W. H. HUDSON, the author of "Idle Days in Patagonia," recently reviewed in these columns, has completed a book called "Birds in a Village," which will be published in a few days by Messrs. Chapman and Hall. The book does not profess to be a serious contribution to ornithology, but is intended rather for the general reader. Among other chapters of interest is one on the introduction of exotic birds, and another on bird-life in London. In the concluding portions of the book the subject of bird-protection is dealt with at considerable length.

A REFERENCE list of the land and freshwater mollusca of New Zealand has been prepared by Messrs. C. Hedley and H. Suter, and appears in the "Proceedings of the Linnean Society of New South Wales," vol. vii., December, 1892. The authors are of the opinion that as the New Zealand fauna becomes better known, its insular character stands out more prominently. Foreign genera, which have been imposed on the fauna, have been eliminated one by one, and many genera which might have been expected to occur, since they are prevalent in neighbouring countries, have not yet been detected. Crosse remarked that "The terrestrial and fluviatile molluscan fauna of New Zealand approximates more to that of New Caledonia, in spite of the considerable distance that separates the two countries, than to that of Australia" (*Jour. de Conch.* xxviii. p. 37), and the authors think his idea has hardly received the attention which it merits.

THE "Tourist Guide to the Continent," published for the Great Eastern Railway Company, has reached its fourteenth year of issue. It is edited by Mr. Percy Lindley, and includes descriptions of things and places of interest in Holland, Germany, Belgium, and Switzerland.

AFTER Mr. Francis Galton, F.R.S., had completed his work on "Finger Prints" he came into possession of the impressions of the fore and middle fingers of the right hand of eight different persons at Hooghly, Bengal, made in the first instance in 1878, and secondly in 1892. These prints have afforded the text for a discussion as to the persistence of patterns, and the result of the decipherment is now published as a supplementary chapter to the above-named book. Though the prints were not obtained by the best means, a comparison of the reproductions of them shows clearly that the "sign-manual" furnishes unquestionable evidence as to a person's identity, and further, the testimony is of such a character that any juryman would be able to appreciate its weight.

WE have received a communication from "Waterdale," in which he calls attention to the fact that he subsequently corrected many of the errors pointed out in the review of his researches which appeared in vol. xlvii. p. 601.

A CORRESPONDENT desires to know where to find any celebrated and artistic hedgerows of elms within about thirty or forty miles of London. Perhaps one of our readers will furnish the required information.

MESSRS. FUNK AND WAGNALL, New York, have just issued a complete prospectus of "A Standard Dictionary of the English Language," a work that has been in preparation for several years, and is now nearly completed. The dictionary will contain 280,000 words in about 2200 pages of medium quarto, and will be embellished with more than 4000 illustrations specially prepared for it. One of the many distinguishing features is the comprehensive provision that has been made for definitions by specialists in various arts and sciences. Handicraft terms have been gathered with great completeness and grouped under the different trades, and by applying a similar system of grouping to the names of fruits, flowers, weights, measures, stars, &c., the facts concerning this class of words are given in a very complete manner. For example, under *constellation* are given the names of all the constellations, and under *apple* are found the names of nearly four hundred varieties. Judging from the specimen pages, and the list of men eminent in science and literature who are concerned in the compilation, the dictionary will be the handiest, simplest, and most trustworthy publication of its kind.

THE *Johns Hopkins University Circular*, No. 106, is chiefly taken up with morphological notes from the biological laboratory of the Johns Hopkins University. Prof. William K. Brooks contributes two important notes on the Salpa embryo, and Mr. M. M. Metcalf describes an apparently new species of Octacnemus, a deep-sea, Salpa-like tunicate. A memoir on the genus Salpa, by Prof. Brooks, will shortly be published. It will contain about three hundred and fifty quarto pages, with sixty coloured plates. The memoir is based for the most part upon material collected by the United States Fish Commission.

"ELECTRIC Light Installations and the Management of Accumulators," by Sir David Salomons, Bart., has reached a seventh edition. This edition has been, to a large extent, rewritten, and is now published by Messrs. Whittaker and Co. under the title "The Management of Accumulators," as the first volume of a series dealing with electric light installations.

Two further papers upon azoimide, N_3H, are contributed to the current number of the *Berichte* by Prof. Curtius. In the first, a brief but important communication, it is shown that azoimide may be prepared directly from hydrazine, $\begin{matrix} NH_2 \\ | \\ NH_2 \end{matrix}$ by the action of nitrous acid.

$$\begin{matrix} NH_2 \\ | \\ NH_2 \end{matrix} + ON{\cdot}OH = \begin{matrix} N\diagdown \\ \| \quad NH \\ N\diagup \end{matrix} + 2H_2O.$$

It is only necessary to lead the red oxides of nitrogen evolved from a mixture of nitric acid and arsenious oxide into an ice-cold aqueous solution of hydrazine hydrate until a vigorous evolution of gas, due to decomposition, commences. A dilute aqueous solution of azoimide is thus obtained with which most of the reactions of the substance can be performed. It is preferable, however, to first condense the red gaseous mixture by means of ice and salt, and to pour the blue liquid, a few drops at a time, into the cold hydrazine solution until the evolution of gas begins. The experiment is unattended by any danger, and is therefore admirably adapted for lecture purposes. Now that hydrazine is so well known and so readily obtained, the sulphate being already a commercial article, this mode of obtaining azoimide will doubtless be adopted by most lecturers for class demonstration, especially as the reaction is one of such fundamental theoretical importance.

IN the second communication Prof. Curtius describes an interesting new organic synthesis of azoimide. When hydrazine hydrate is caused to act upon a salt of diazobenzene, a fugitive compound is obtained of the constitution indicated by the formula $C_6H_5N : N.NH.NH_2$. This compound might be expected to decompose in two ways, breaking up either at the double linkage or at the single linkage between the NH and NH_2 groups. According to the former mode there would be a migration of two hydrogen atoms from two different nitrogen atoms to a third nitrogen atom with production of aniline and azoimide, $C_6H_5N : N.NH.NH_2 = C_6H_5NH_2 + N_3H$. According to the latter mode of decomposition one hydrogen atom would migrate and form ammonia with the last amido group, leaving diazobenzene imide, thus: $C_6H_5N : N.NH.NH_2 = C_6H_5N_3 + NH_3$. As a matter of fact both decompositions occur, the latter somewhat predominating. It is quite easy, however, to isolate 10 per cent. of the theoretical yield of azoimide. Equi-molecular saturated aqueous solutions of hydrazine sulphate and diazobenzene sulphate are mixed and poured into a 3 per cent. solution of sodium hydrate. A turbidity is at once produced, which eventually coalesces into an oil. This is extracted with ether and ammonia, expelled from the aqueous solution by boiling. The liquid, which contains the sodium salt of azoimide, is then rendered slightly acid with sulphuric acid and distilled, when azomide passes over along with the steam. The ethereal extract contains the aniline together with diazobenzene imide produced according to the second mode of decomposition.

NOTES from the Marine Biological Station, Plymouth.—The arrival of Midsummer renders desirable a summary of the records which have been made in this paragraph during the past six months of the breeding seasons of marine animals at Plymouth. The records have approximately indicated the *commencement* of the breeding seasons; but it should be premised that in the great majority of instances the period of reproduction is prolonged throughout the summer months, and is already at an end only in a few isolated cases. The following have been recorded:—The Gymnoblastic Hydroids *Tubularia bellis*, *Clava multicornis* and *cornea*, *Eudendrium ramosum* and *capillare*, together with the Anthomedusæ *Rathkea octopunctata* (now over), *Bougainvillea ramosa*, *Amphinema Titania*, *Sarsia prolifera* and *tubulosa*, *Podocoryne carnea* and *Corymorpha nutans*; the Calyptoblastic Hydroids *Halecium* (*halecinum* and *Beanii*), *Plumularia setacea* and *pinnata*, *Antennularia ramosa* and *antennina*, *Sertularella* (*Gayi*), *Sertularia argentea* and *pumila*, *Hydrallmania* (*falcata*), *Gonothyræa Lovéni*, together with the Leptomedusæ *Obelia lucifera*, *Clytia Johnstoni*, *Irene pellucida*, *Phialidium variabile*, *Laodice cruciata*, *Thaumantias octona*, *Forbesii*, and *Thompsoni*; the Ctenophore *Hormiphora plumosa*; the Actinians *Cereanthus* (*Arachnactis*,—now over), *Halcampa chrysanthellum*, *Cereus pedunculatus*, *Bunodes verrucosa*, *Urticina felina* and *Actinia equina*; the Nemertines *Cephalothrix linearis* and *bioculata*, *Amphiporus dissimulans*, Riches (= *pulcher* of previous record, March 30), *Nemertes Neesii*, and *Lineus obscurus*; the Polychæta *Phyllodoce maculata*, *Cirratulus cirratus*, *Polydora* (*flava ?*), *Sabellaria spinulosa*, and various *Terebellidæ* and *Serpulidæ*. The Polynoïd larvæ which swarmed in the Sound in the early Spring are no longer to be obtained. The Mollusca, Crustacea, Echinodermata and Chordata will be summarised next week.

THE additions to the Zoological Society's Gardens during the past week include three Peba Armadillos (*Tatusia peba*, ♂ ♂ ♀) from South America, presented by Mr. Woodbine Parish; two Brazilian Cariamas (*Cariama cristata*) from Paraguay, presented by Mr. A. E. Macalister Hadwen; five Spotted-billed Ducks (*Anas pœcilorhyncha*, 4 ♂ 1 ♀) from India, presented by Sir E. C. Buck, C.M.Z.S.; a Guillemot (*Lomvia troile*) British, presented by Mr. T. A. Cotton, F.Z.S.; two Chiff-chaffs (*Phylloscopus rufus*), two Yellow Wagtails (*Motacilla flava*) British, presented by Miss McGill; a Naked-necked Iguana (*Iguana delicatissima*) from the Caicas Islands, West Indies, presented by Lady Blake; a Lobed Chameleon (*Chamæleon parvilobus*) from Barberton, Transvaal, presented by Dr. Percy Rendall; two Capybaras (*Hydrochærus capybara*) from South America, purchased; an English Wild Bull (*Bos taurus*, var.), a Burrhel Wild Sheep (*Ovis burrhel*, ♀), a Derbian Wallaby (*Halmaturus derbianus*, ♀) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

A NEW VARIABLE *u* CYGNUS.—In photographing the region of α Cygni, Dr. Max Wolf (*Astronomischen Nachrichten*, No. 3168), on examining the plates, has found a new variable, its position for 1893·0 being R.A. 20h. 47·2m., Decl. + 45° 49′. The star, he says, is very easy to find, lying as it does in the south right-angle corner of a right-angled triangle, the stars in the other corners being B.D. stars + 45°·3300 and + 45°·3302.

The brightness, as obtained from the plates, gave the following numbers:—

				m.
1890	...	Dec. 12	...	13
1891	...	June 1	...	12
1891	...	Sept. 7	...	12
1893	...	May 14	...	12·5

Finlay's Comet (1886 VII.).—The following ephemeris for this comet is continued from *Astronomischen Nachrichten*, No. 3164:—

12h. M.T. Paris.

1893.		R.A. app. h. m. s.		Decl. app. ° ′
June 22	...	2 19 1	...	+11 14·5
23	...	23 47	...	11 40·6
24	...	28 33	...	12 6·3
25	...	33 19	...	12 31·6
26	...	38 4	...	12 56·5
27	...	42 50	...	13 21·0
28	...	47 35	...	13 45·1
29	...	52 20	...	14 8·7

The comet during this week lies towards the southern part of the constellation of Aries, passing near Aries 38 on the 26th.

A Bright Comet?—A telegram which we have received from Kiel contains the following data obtained on June 5 and 12 with regard to a probable comet:—

1893.		R.A. h. m.		Decl. ° ′
June 5	...	9 57·1	...	+14 21
12	...	10 4·3	...	+20 56

This object lies somewhere in the region of η Leonis.

Observations of Nebulæ.—In *Astronomischen Nachrichten*, No. 3167-68, Dr. Rudolf Spitaler communicates the observations of nebulæ that he has recently made with the 27-inch Grubb refractor of the Observatory in Vienna. He also compares the brightnesses obtained by him with those in Dreyer's new General Catalogue of Nebulæ and Clusters. In addition to the mean places of these objects and of the comparison stars employed for the years 1891 and 1892, he gives several notes and a plate illustrating many of the nebulæ.

The Yerkes Telescope.—*Astronomy and Astrophysics* for June gives some particulars about the Yerkes telescope, from which we make the following few notes. The great tube pier and clockwork are being built by Messrs. Warner and Swasey, the makers of the Lick 36-inch. The column will be made in five sections, each section except the base one (which will weigh about 18 tons), weighing about 5½ tons each. The column rises 31 feet 4 inches from the base. The pier head weighs 5½ tons; thus the total weight of the column and head reaches about 45 tons. The polar axis, which is of steel, is 15 inches in diameter, 13 feet long, and weighs about 3½ tons, the declination axis measuring 12 inches in diameter and weighs 1¾ tons. The length of the sheet steel tube (exclusive of eye end) measures 62½ feet, its greatest diameter reaching 52 inches, and weighs 6 tons. The focal length of the objective is about 64 feet. All quick and slow motions and clamps can be operated either from the balcony, eye end, or floor, by hand or by electricity as may be required. The floor will be an elevating one like that at the Lick. The telescope weighs in all 75 tons, and an idea of its size may be gathered from the fact that "when the telescope is pointed to the zenith, the object glass will be 72 feet in the air, or about as high as a seven-story house."

The Smithsonian Report for Year Ending 1892.—Among the many interesting points to which Mr. S. P. Langley, the secretary of the Smithsonian Institution, refers to in this report, we note the following: The Smithsonian Astrophysical Observatory still occupies the "temporary wooden shelter on the grounds." Although the money for the permanent building is in hand, the Institution is only waiting for the action of Congress to provide a site. With respect to the work that is being done and is proposed for the future, Mr. Langley makes a special reference. The branch of astronomy to which the resources of the Observatory will be devoted will be that of exploring the great unknown region in the infra-red end of the spectrum by the method recently improved by Mr. Langley himself. The secretary refers also at some length to the recent gift of 200,000 dollars to the Institution by Mr. Thomas George Hodgkins, of Setauket, N.Y., the interest on 100,000 dollars of which is to be used for the general purposes of the Institution on the "increase and diffusion of knowledge among men," provided that the interest on the remainder be used in the investigation of the properties of atmospheric air considered in its very widest relationship to all branches of that science. The report contains the result of several communications on the subject. At some length are treated also reports on the National Zoological Park, which, by the way, seems to be in a not very flourishing condition, on the financial aid given to Research, the National Museum, Bureau of Ethnology, &c., which we must pass over, as they do not appertain directly to the subject of this column. One point we must refer to is the proposed plan of publishing a work on the moon which shall represent the present knowledge of her physical features. The Institution is already in communication with some of the leading observatories of the world, and it is hoped that "a series of photographic representations of hitherto unequalled size and definition, which shall represent the moon's surface as far as possible on a definite scale, and *entirely* without the intervention of the draughtsman." We heartily wish the co-workers in this scheme success, for have we not now, with the present state of photography and fine instruments, a good basis to work upon.

THE MORPHOLOGY OF THE VERTEBRATE EAR.[1]

I. THIS elaborate and important monograph monopolizes the first two parts of the sixth volume of the *Journal of Morphology*. It is the second of a projected series on "Vertebrate Cephalogenesis." Its predecessor was published in the same journal two years ago, and the instalment now under consideration has been anticipated by three shorter communications (Nos. 5, 7, and 8 of the literature cited) of a distinctly sensational character. The 320 pages of contents are illustrated by 26 simple woodcuts; and by 12 magnificent folding plates, printed in colour, and bearing the charmed names of Werner and Winter.

The monograph is subdivided into six sections, with a recapitulatory one, and is based upon the morphological study of the ears of adequate representatives of leading classes and orders of vertebrates, and upon experimental observations chiefly involving the pig and cat. The author's work bears every trace of extreme caution in manipulation, and he lays much stress upon deceptive effects produced by the action of reagents—for example, the knobbing and apparent collar-formation met with in the hair-cells of the avian basilar organ. In seeking to correct certain kindred errors which have arisen during the work of his predecessors, the author concludes (i.) that Retzius' "nerve plates" of the avian labyrinth are "products of the maceration process"; (ii.) that the "horseshoe figure," which the same investigator attributed to the mammalian hair-cell, is an "optical effect"; (iii.) that the continuity between the pillar-fibres and basilar membrane described by Noel "does not exist"; and (iv.) that the basilar membrane itself—defined as "a modified portion of the skin of the head which forms first and last the floor upon which the sense organs rest"—is not elastic enough "to serve for the transmission of the delicate undulations which it has been supposed to transmit." While denying the presence of "spiral nerves" in the cochlea, he concludes that they "exist in the living condition as delicate walled but relatively large lymph channels"; and concerning the very involved question of relationship between the nerve fibres and hair-cells, he asserts that the ultimate filaments are "continuations of the nerve into the hair processes." The "membrana tectoria" of the mammal is said to be but a "cupula terminalis-like structure produced by the gluing together of the hairs of the sensory cells of the organ of Corti, and the breaking away of the whole from the cells which bear them"; and it is incidentally remarked that as found in ordinary preparations it is but "an artifact produced by the use of reagents." However much disposed to accept this very revolutionary deduction, we await confirmation of certain of the author's detailed observations, before fully acquiescing in the belief that "the membrana tectoria, the membrana reticularis, Loewenberg's net, and the three or four main trunks of the system of spiral nerves of the cochlea" so-called, are one and all pure artifacts.

In the course of his inquiry the author has been led into a re-examination of the detailed relationships of the auditory nerves; and in this department he has done a lasting service by sufficiently emphasizing Breschet's long-recorded discovery that the auditory nerve of man is "divided into two branches, each of which supplies semicircular canal organs" (*i.e.* that

[1] "A Contribution to the Morphology of the Vertebrate Ear, with a Reconsideration of its Functions." By Howard Ayers, Director of the Lake Laboratory, Milwaukee, Wis., U.S.A.

the posterior ampulla is innervated from the cochlear nerve), the unfortunate bearings of which upon certain much more recent physiological speculations he is not slow to point out (p. 148). The thanks of all teachers are similarly due to the author, for having introduced the peculiarly appropriate term "ama" for that second and non-sensiferous enlargement of the canals met with in the lower and the highest classes of vertebrates, and for the substitution of "external" for the misleading "horizontal" canal.

One very remarkable discovery, which the author deals with only too casually, is that "in many forms of Elasmobranchs the ear contains scarcely any crystals, and not unfrequently sand grains." The interest of this, by analogy to Hensen's well-known experimental observations upon the Decapod Crustacea, will sufficiently appeal to all zoologists; and we sincerely hope the author will early furnish us with particulars concerning it.

II. Revolutionary as may be some of the author's conclusions above cited, the refrain of the major part of his morphological inquiry is, on the whole, no less so. It runs as follows:—"There can be no doubt that the internal ear develops from superficial canal organs"; that it is primarily subdivided into anterior and posterior portions; and that a "fateful distortion," under which the great development of the cochlea drags the posterior half downwards, has "perhaps more than anything else" deceived us and "retarded our progress in the knowledge of the significance" of its parts. Thus it is that the author gives definiteness to a view which, although it unconsciously dawned with Leydig's recognition of structural similarity between the auditory and tegumental-canal sense-organs of the Ichthyopsida, was first definitely formulated by Beard. He takes his stand upon Beard's brilliant generalization, as modified by the acceptance of Froriep's interesting correction (p. 314), and by certain considerations arising out of his own inquiry. In the performance of this task the author has been shoulder to shoulder with Mr. Allis, co-editor and joint founder of the *Journal of Morphology*, and author of one of the most remarkable papers which its pages have yet borne, viz. that upon "The Anatomy and Development of the Lateral Line System in Amia Calva," duly noted in these pages (NATURE, Aug. 29, 1889), and nothing is more apparent than that he has sought to extend the laws of growth which Allis discovered for the lateral line organs to the internal auditory one. His leading deduction that the last named structure consists of "a symmetrical group" of the organs in question chiefly rests upon the following discoveries and allegations, apart from any question of general structural resemblance between the two, viz. (i.) the lineally recurring (antero-posterior) symmetry of the parts of the labyrinth; (ii.) the duplication of the endolymphatic ducts in Cyclostomes and some Elasmobranchs; (iii.) the double and repetitional nature of the auditory nerve—that being regarded as a derivative of "two distinct cranial nerves," consisting of an anterior (utricular) fasciculus in anastomosis with the facial, and a posterior (cochlear) one, either in astomosis with the glossopharyngeal, or totally independent; and (iv.) an attempt to show that the *macula acoustica neglecta* is an "abortive second horizontal canal organ." Although inclined to accept the general tenor of the author's broader morphological conclusions, we cannot concur in the last cited one. He formulates it almost entirely upon the study of nerve distribution; and, by his own showing (pp. 28, 29) the sensiferous area in question might well have had an independent origin. The conclusion does not, however, materially affect the author's dictum, and in respect to it he seems to have been carried away by a bias in favour of Allis, which elsewhere reappears (pp. 275, 277, and 283), and culminates in the unwarrantable assertion (p. 308) that "the semicircular canals of the ear are simply remnants of the canal system of the surface" (p. 318) "not known to have any other function than the one inherited from their ancestors, viz. that of serving as mechanical protectors of the sense organs," and that they are to be classed with such structures as valves in the horizontal veins . . . the vermiform appendix . . . and atavistic muscles" (*sic*). Having sought to show that the "canal organ has been gradually losing ground" during the progress of descent with modification, the author argues (p. 235) that the future human ear "will not retain much else than the cochlea"! What of the adherents to the bagpipe? We would recommend a periodical examination of their ears to the author's notice. Statements of the order here commented upon are indicative of haste and over-enthusiasm, while others, to the effect that (p. 47) "the cells involuted with the sensory structures "merely" serve as a lining of the auditory canal chambers," and that the otoliths, which they secrete (p. 309) "are to be considered as essentially foreign bodies . . . tolerated because of the impossibility of getting rid of them . . . and the result of the secretive action of the ectoderm cells, which in ancestral forms produced the surface scales," are little short of nonsensical.

With Fritsch, the author regards the Savi's vesicles of the *Batoidei* as derivatives of "the widespread open canal type" of organ; and by no means the least striking portions of his treatise are those in which he attempts to prove (i.) that the semicircular arch of *Myxine* is "composed of the anterior and posterior vertical canals of the Gnathostome vertebrate ear"—deducing an argument in favour of the non-degeneracy of the *Marsipobranchii*, and (ii.) "that a comparison of the ears of Myxine, Petronnyzon, Dasyatis, Torpedo, and Man clearly shows the connection of the [endolymphatic] duct with the utricular and sacular chambers to be a fundamental condition, and not a secondary acquirement."

III. That the physiological aspects of the author's inquiry might be expected to be no less sensational than the morphological ones, is sufficiently clear from his earlier surmise (pamphlet No. 7 of literature cited) that (p. 8) "when one considers the truly wonderful auditory powers" of the mocking bird, "it becomes evident that we must seek for some explanation which does not involve the piano-string hypothesis," and that (p. 9) "it is perfectly obvious that we do not need an internal ear in the vertebrate organization for the perfect exercise of the function of equilibration, since in Amphioxus the organ is absent, and in higher forms the auditory nerves may be destroyed without destroying this function." Little wonder, then, that the author should denounce both the "statical" theory of Goltz, and the more recent "dynamical" one of Cyon, Crum-Brown, and later experimentalists. His attitude towards the majority of his predecessors is best expressed in his remark that "all the phenomena following canal section in mammals and in birds are nothing more than the results of brain lesions such as are entirely inadequate to explain" them.

Availing himself of the observations of Munk, that, whereas in the dog, destruction of the ear, which may lead up to fatty degeneration of its inner constituent, is "always followed by dizziness and equilibrative disturbances, such disturbances do not appear when the cochlea is preserved," and of others akin to them he concludes that, provided the semi-circular canals "have a function, it is not either statically or dynamically equilibrative." Reference is made to Steiner's important observation that whether (in the shark) "the semicircular canals were removed or not," disturbance of the otoliths covering the utricular sense organ, invariably instituted rolling movements, usually towards the side disturbed; but the author is silent concerning Engelmann's attempt to assign distinct functions to the cristæ and maculæ with their associated otolithic masses. Indeed, his opening statement (p. 237) that "we have very slender foundation for forming final judgments of the functional relations of any parts of the internal ear, and that at present what we imperatively need is not speculation, but *experimentation*," well defines our position to-day, when the sum of the author's own experimental observations are taken into account. The physiological section of his work is much weaker and less extensive than its morphological ally.

IV. The author is to be congratulated upon an unusually speculative treatise, embodying a substratum of solid work. As a "paper" it is, in its bulkiness, a sort of awful example fit to rank with that of his countryman Mark on the egg of *Limax campestris* (*Bull. Mus. Comp. Zoöl.*, vol. vi., 445 pages in all). The publication of such voluminous treatises in any but book form, provided with an analytical index, is unjust to both author and reader. It is a gross mistake, and the author has but himself to thank if he escapes proper recognition in consequence. Much of the said bulkiness of the present treatise is due to the incorporation of needlessly lengthy citations from foreign writers, which, permissible in a book, are out of place in a "paper" intended for specialists possessing a full knowledge of current literature. We could have wished, instead of these, a recognition and an explanation of topics untouched; for example, of the circular condition of the posterior canal among the depressed Batoidei, which the author's remarks on pp. 13, 16, 222, and 223 by no means sufficiently express, and which is inexplicable on his belief that "the mechanical forms active in the modelling of the ear are for the most part the inherited tendencies of cell growth acquired as legacy from the canal organs of the surface." Among important topics which the author ignores, and upon which we could have wished his opinion, are Chatin's alleged discovery of all intermediate stages between the rod-bearing and ciliated cells of the Batrachian auditory epithelium, and the views of Engelmann, Chun, and Yves Delage, arising from the experimental study of the otoliths in Ctenophora, Mollusca, and Crustacea. The latter are by no means reconcilable with the author's bold assertion that "the functions of the otoliths are entirely unknown." In dealing with the "chalk-sacs" of the amphibia, the author remarks (p. 21) that their "morphological as well as physiological significance" is still unknown. He ignores the fact that Lenhossek has shown them to be tubular glands and named them; and this is very remarkable, as, while he makes no mention of that author's paper, he acknowledges one by Coggi, in which it receives ample recognition. G. B. H.

PERSPECTIVE AND COLOUR.

IN *Brain*, Parts LXI. and LXII., which have just been published, occurs an interesting article by Prof. Einthoven (of Leyden) on the production of shadow and perspective effects by difference of colour. The following is an account of the phenomena:—

Difference of colour may, under certain circumstances, be the cause of an apparent difference in distance.[1] To observe the phenomenon, it is only necessary to glue different coloured figures, such as letters of blue and of red paper, to a screen of black velvet and to look at them from a suitable distance. In the experiment about to be described, Roman capital letters of about eight by four centimeters were used, the screen being placed at about three meters distance from the observer.[2]

Under these conditions it appeared, both to Prof. Einthoven and to others who he interrogated, that the red letters were nearer than the blue. Obviously, the phenomenon might be explained by difference in accommodation. In order to see the red letters distinctly, a greater amount of accommodation is necessary than in focussing the blue ones, and the greater sense of effort might account for the notion of the red letters being nearer. This accommodation hypothesis, plausible as it seems, cannot however be accepted as a satisfactory explanation of the phenomenon. Several observations tell against it, notably this: that there are about as many persons who see the blue letters before the red, as there are those who see red before blue. In the second place, the apparent difference in distance—so distinct to binocular vision—disappears almost wholly with the closure of one eye. Looked at with one eye only, and for some length of time, the letters appeared to be lying in the same plane, but each time that the other eye was opened the difference in distance obtruded itself irresistibly.

The amount of difference remains constant, and can be estimated with considerable accuracy, in the same way as in making a stereoscopical observation. The question therefore suggested itself, whether we had not here to deal with real stereoscopy? The answer to this question is an affirmative. Brücke[3] has shown by means of a simple experiment that the retinal images of differently coloured points are shifted with respect to one another. Looking with one eye at a narrow vertical strip on a black background, the upper and lower thirds of the strip being red and the middle third blue, Brücke observed that the blue part deviated to one side, the two red parts to the other side. By covering either eye alternately, a deviation of the blue and red parts in opposite directions will be observed; and, on both eyes being used, the notion of a difference in distance is proved by the combination of the two images in such a way that the parts that deviate to the nasal side constitute the nearer image; the parts that deviate to the temporal side, the further image. The stereoscopical effect is, however, more distinct and convincing with the coloured letters than with the strip used by Brücke.

The cause of the relative removal of the differently coloured images lies in the eccentricity of the pupil, as may be demonstrated experimentally. The pupils may be made highly eccentric by covering them partially. Partial covering on the nasal side is equivalent to a removal of the pupil to the temporal side, and conversely, covering the temporal side is equivalent to removal to the nasal side. With a nasal eccentric pupil a shifting of the differently coloured images in one direction will be observed; with a temporal eccentric pupil the shifting will be in the other direction.

The effect of an artificial eccentricity of the pupil is surprising when both eyes are used. Anyone who sees the red letters before the blue has only to cover his pupils symmetrically on the temporal side, when he will observe the red letters retreat and soon appear to be behind the blue. On covering his pupils symmetrically on the nasal side, the red letters come forward more and more, and seem at last (experimenting at a distance of four or five meters) to remain several decimeters in front of the blue. A person who sees the blue letters before the red, has only to cover his pupils on the nasal side, when he will observe that the distances change, the red coming forward and the blue shrinking back.

Lately, however, Dr. A. D. Waller has found that on repeating the experiment with a seemingly slight modification, he obtained the same effects with one eye alone. He used as a test object rings of blue paper on a red ground, or of red paper on a blue ground, and found that the nasal pupil of the left eye gives the same appearance of circular trenches or hillocks as does the temporal pupil of the right eye.

This observation has been the motive to a more thorough study of the phenomenon.

On looking with the right eye and a temporal pupil at red rings on a blue paper, the rings appear as circular hillocks when the paper is held to the left, and also sloping in that direction. One seems to be looking against the dark edges of a thick red ring fixed upon the blue paper. With a nasal pupil the red rings appear as circular trenches.

The phenomenon is the more striking in proportion to the purity of the colours used. The pupil must be made sufficiently eccentric and in a suitable direction by means of a black screen that covers it from one side, or better still, by means of a stenopæic apparatus. The pupil must not be too narrow, and the whole eye should be wide open and well-directed, so as to avoid any partial covering by the nose, eyelid, or lashes. Lastly, it is not desirable to keep the eccentricity of the pupil constant for more than a brief period. For if one stares at the rings a long time with unmoved pupils, all appreciation of distance is lost, as in so many cases where only one eye is used, and the rings may even seem to lie in a plane that intersects the plane of the blue paper perpendicularly. If, on the contrary, one shifts the screen or the stenopæic apparatus now and then the rings appear to rise and sink, and, under the above-mentioned conditions the rising will be with temporal pupil, the sinking with nasal pupil, and in a way almost as striking as if they were seen stereoscopically.

Prof. Einthoven proves mathematically that the explanation of the phenomenon is found in the appearance of shadows.

THE FLORA OF GREENLAND.

IN 1891 Dr. William H. Burk accompanied, as botanist, the party which escorted Lieut. Peary to his winter quarters in McCormick Bay. A number of plants were collected and taken to America, but they had barely been determined before an expedition was organised to search for Lieut. Peary, and Mr. William G. Meehan was appointed botanist to it. This was just a year ago. Mr. Meehan was also fortunate enough to obtain specimens, and a catalogue of the plants collected in both cases was communicated to the Academy of Natural Sciences of Philadelphia on April 11. Some idea as to the character of the catalogue will be obtained from the following introduction to it:—

The range of territory covered by Dr. Burk and Mr. Meehan was between about latitude 63° and above 78° or between Godthaab and Littleton Island.

As nearly the whole collection was repeated by each collector, it may be taken as a fairly complete flora of that portion of the territory of Greenland.

Before starting in their respective journeys, both Dr. Burk and Mr. Meehan were instructed to examine as far as possible

the influence of ice sheets on the geographical distribution of plants. Prof. Thomas Meehan, the father of the latter, in a "Catalogue of Plants collected in July, 1883, during an Excursion along the Pacific Coast in South-eastern Alaska,"[1] had given reasons for believing that plants did not merely advance in the wake of retreating glaciers, or push into growth from material brought down in their advance, but that when caught under the mass of flowing ice, would remain for an indefinite period, retaining vitality, and push again into growth when the ice retreated. Prof. Meehan was led to this conclusion from finding no annual plants among those collected in the immediate wake of retreating glaciers in Alaska, while the actual number of species of perennials collected in such locations would be as great as if much time had been given for a floral advance. He had but little opportunity for actual observation as to the plants brought down with the earth carried on the ice, but so far as this went only *Epilobium latifolium* and *Dryas octopetela* were found in this condition, and scarcely any plants were observed on recently deposited moraines. These and some other facts led to the hypothesis that the plants were not migratory, but had held their position through the whole icy period.

These facts were supported by the determination of the existence of much the same flora in isolated spots of land recently bared by the névé of the inland ice, as grow away from the margins of the ice sheet, while the finding of living willow trunks, grass, and perennial plants of many years' growth close to the edges of retreating glaciers, seem to place the point beyond any reasonable doubt, especially when, after careful survey, through the construction and positions of the glaciers, there was the absolute certainty that the plants could not have been deposited by lateral, medial, or terminal moraines, though they might have been by ground moraines—a circumstance which would settle Prof. Meehan's position affirmatively beyond dispute, since the ground moraines are borne under the flowing ice rivers. Abundant vegetation was also found in nunataks—peaks of land projecting above the glaciers or ice cap—but little significance was placed on this circumstance, since all such nunataks visited were within a reasonably close proximity to the main land masses, and the vegetation might readily have sprung from seeds blown there by the winds or brought by mud on the feet of birds. But the demonstration of aged living plants in the other situations named must have a strong bearing on the discussions involved as to the influence of the ice age on the distribution of plants over the surface of the earth.

The abundance of lichens is characteristic of the flora of Greenland. Rocks supposed from a distance to be naturally coloured are found on closer inspection to derive their hue from a complete investiture of some lichen. In this particular the crimson cliffs, beginning at Cape York and extending many miles northward, are a conspicuous example. These cliffs, rising sheer from the water's edge to heights of from seventeen hundred to two thousand feet or more, though of grey granite, show no spot of the intrinsic colour even on being nearly approached, but present a uniform red appearance over their whole surface from a large orange red lichen which covers them.

In view of Schwendener's theory that lichens are but symbiotic forms of algæ and fungi, it is to be regretted that the probably rich fields afforded by the latter named great families in this region have yet to be investigated.

Mosses are even more abundant than lichens. They grow in such vast quantities in spots, that their light or dark greens are visible often for some miles away, brightening the otherwise bleak shores wonderfully. Their persistence in growth under apparently adverse circumstances is also remarkable. No obstacle save the sea seems sufficient to stop their progress. Even dead glaciers have been and are being buried under the steady march of these cryptogamous plants. Mosses fulfil the same duty in Greenland that other forms of plant life perform in more favoured climes, and the amount of rich vegetable matter being deposited by them may be of great value in the future of that great arctic island.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Rev. Bartholomew Price, Master of Pembroke College, has been added to the electors to the Savillian Chair of Astronomy on the present occasion.

SIR HENRY HOWORTH, F.R.S., has had the honorary degree of D.C.L. conferred upon him by Durham University.

OXFORD has conferred the degree of M.A. upon Dr. W. B. Benham, Aldrichian Demonstrator.

MR. W. FISHER, late Conservator of Forests in the North-West Provinces of India, has been appointed Assistant Professor of Forestry at Cooper's Hill.

SCIENTIFIC SERIALS.

American Journal of Science, June.—Electro-chemical effects due to magnetisation, by George Owen Squier.—Nikitin on the quaternary deposits of Russia and their relations to prehistoric man, by A. A. Wright. A summary of the views laid before the International Congress of Archæology in Moscow, 1892, by the Russian geologist, Mr. S. Nikitin, regarding the palæolithic and neolithic epochs in European Russia, and their coincidence with the geological divisions of pleistocene and modern.—Rigidity not to be relied upon in estimating the earth's age, by Osmond Fisher. A criticism of Mr. Clarence King's estimate of the probable age of the earth on the ground of its assumed rigidity not being an established fact. The argument derived from tidal action is fully discussed. Had the solid part of the earth so little rigidity as to allow it to yield in its own figure very nearly as much as if it were fluid, there would be very nearly nothing of what we call tides—that is to say, rise and fall of the sea relatively to the land—but sea and land together would rise or fall a few feet every twelve lunar hours. This would be the case if the geological hypothesis of a thin crust were true. This is the argument for tidal rigidity as enunciated by Kelvin. But this does not take into account the horizontal motion of the water. It rests upon the equilibrium theory of tides as against the canal theory. The latter has been symbolically worked out by Prof. G. H. Darwin. If the earth's interior be assumed to be a liquid of small viscosity, the bodily tide at its equilibrium value will have a height of $1\frac{3}{4}$ feet. This will diminish the hydrodynamical tide by not more than a fifth of its value, and it is quite possible that the tides we actually experience may be tides thus diminished by the fluidity of the earth's interior.—On the treatment of barium sulphate in analysis, by J. I. Phinney. The author shows that alkaline chlorides contaminate barium sulphate thrown down in the presence of an excess of sulphuric acid, and that the process of purifying by hydrochloric acid is inefficient. The only good method for purification is either to fuse, according to Fresenius, with sodium carbonate, extracting and reprecipitating as sulphate, or to evaporate from solution in concentrated sulphuric acid according to Mar.—On the nature of certain solutions and on a new means of investigating them, by M. Carey Lea. The solutions in question are those of sulphates which were tested for free sulphuric acid by a solution of iodoquinia, a very delicate and trustworthy test. Solutions of heavy metallic sulphates, with the exception of ferrous sulphate, contain no free acid. All sesquisulphates examined were dissociated in solution. So were acid salts and alums, with the exception of chrome alum.—Also papers by Messrs. Fairbanks, Moses, Penfield, Johnson, and Pupin.

Bulletin of the New York Mathematical Society, vol. ii. No. 8 [May, 1893, New York]. This number opens (pp. 175–178), with a review by Miss C. A. Scott of Prof. W. B. Smith's "Introductory Modern Geometry of Point, Ray, and Circle" (see NATURE, vol. xlvii. p. 532). We endorse her closing remarks that the usefulness of the book would be greatly increased if he were to translate his work into ordinary mathematical English.—Prof. Echols contributes an interesting note, biographical and otherwise, entitled Wronski's expansion (pp. 178–184). The expansion was presented by Hoëné Wronski in 1810, to the French Academy of Sciences, and is as follows:—$f(x) = a_0 + a_1\omega_1 + a_2\omega_2 + \ldots$ *ad infinitum*, where $f(x)$, ω_1, ω_2, ... are arbitrary functions of x, and a_0, a_1, ... are independent of x. The law of formation of the coefficients he calls "la loi suprême."—Dr. Cole, in a note on the substitution groups of 6, 7, and 8 letters (pp. 184–190), furnishes a list of over forty omitted groups supplementary to the lists given by Messrs. Askwith and Cayley in vol. xxiv. of the *Quarterly Journal of Mathematics*.—The *Mathematical Bibliography*, by A. Ziwet (pp. 190–192) gives in some detail an account of the new *Revue Semestrielle des Publications Mathématiques*, &c., issued by the Mathematical Society of

[1] Proceedings of the Academy of Natural Sciences of Philadelphia, 1884.

Amsterdam, to which attention has been drawn in our columns. The notice is on the whole favourable to this new venture.—The notes and new publications are well up to date.

Meteorologische Zeitschrift, April.—On the hypotheses of the oscillations of the so-called maximum zone of the aurora, and the peculiarities of the development of the aurora in this zone, by A. Paulsen. In 1872 Prof. Fritz asserted that the winter minimum of the aurora diminished with increase of latitude, and in 1880 M. Tromholt endeavoured to show that the maximum zone is in a state of continual oscillation, as it makes not only a yearly and eleven-yearly movement, but also a daily periodical change of position. Also that auroræ are more frequent in the morning hours than in the evening, and therefore that the maximum zone shifts to the northward during the night. The object of Dr. Paulsen's paper is to refute these assertions, and he quotes observations to show that the movement of the zone of greatest auroral display during the course of the night is not towards the north, and states that no single phenomenon exists that can be explained by a daily oscillation of the maximum zone, but that, on the contrary, all that we know about the daily range of the aurora points to the fact that no such movement can exist.—Relations of daily synoptic weather charts to the general circulation of the atmosphere, by E. Herrmann. Starting from the point of view that the resultants of the forces of the earth's rotation and of centrifugal force, in a stationary condition of the atmosphere, must be normal to the areas of equal pressure, the author shows how the normal distribution of pressure is solely a result of the difference of rotation of the atmosphere round the earth's axis, and of the rotation of the earth itself. On the basis of the distribution of pressure acccording to Maury's zones, there result three zones in each hemisphere:—An equatorial zone of easterly winds, a zone of westerly winds, and a polar zone of easterly winds, with corresponding changes of pressure. It follows from the decrease of temperature towards the pole that at a certain height the zone of westerly winds extends over the zone of easterly winds. The daily positions and extent of the zones are determined by the distribution of pressure in all latitudes, and their existence is a necessary consequence of the principle of the preservation of areas, but applied to the whole atmosphere, and not to individual particles as Ferrel has done. The author urges the importance of the continuance of synoptic charts, and of the desirability of telegraphic reports from Iceland and the Azores.

Bulletin de l'Académie Royale de Belgique, No. 4.—The most interesting paper is one by G. Van der Mensbrugghe on negative hydrostatic pressure. It is well known that any horizontal layer of a liquid in equilibrium supports a hydrostatic pressure equal to the weight of a column of liquid, whose base is equal to the area of the layer considered, and whose height is the vertical distance of the layer from the surface. The author investigates the pressures existing in layers lifted up *above* the level, whether by atmospheric pressure, capillarity, or otherwise. In this case the hydrostatic pressure will be similarly calculated, but will be negative, so that it must be subtracted from the external pressure upon the surface of the liquid in order to obtain the true pressure on the layer. This conclusion is illustrated by a series of striking experiments. A test-tube was filled with water and withdrawn, mouth downwards, from the tank, leaving the mouth an inch or so below the level. A U-tube was closed with the thumb at one end, while the other was inserted in the test-tube. On releasing it, air was sucked into the test tube and the liquid reduced to the exterior level. A long cylindrical tube of paper, similarly filled with water and withdrawn, was flattened more and more towards the top, owing to the atmospheric pressure exceeding that of the liquid inside. The same reasoning applied to cases where the liquid was raised by capillary action, the distribution of pressure being the same as if the tubes had been closed at the capillary surfaces. A wide tube was provided with a closely-fitting cork, through which was passed a very fine tube. The liquid was held suspended in the wide tube owing to the capillary action of the surface in the thin tube, which was 4 cm. above the level. On introducing a U-tube as before, the water was again expelled by the air rushing in, and reduced to the external level.

Bulletin de la Société des Naturalistes de Moscou, 1892, No. 3.—Sources for the flora of the Kieff educational district (Kieff, Volhynia, Podolia, Tchernigov, and Poltava), by Comte Bourdelle de Montrésor, being a full bibliography of all publications relative to the subject.—Contributions to the ornithology of the Transcaspian region, according to the researches of M. Thomas Barey, by J. Stolzmann. M. Barey travelled in the region in 1889–91 for the Branicki Museum of Warsaw. Of the 230 species mentioned in the detailed list now given, 17 are new for the region.—On the alkalies of the blood and the lymph, by J. M. Syechenov. Blood being not only the store for the food materials of the organism, but also the medium for breathing, it is desirable to ascertain the means of maintaining the composition of blood which is necessary for that purpose. The fact that the carbonate of sodium from the pancreatic and intestine juice enters the blood, is considered as a process for feeding the blood with necessary alkalies.—The Upper Tithonic deposits of Central Russia; note by N. Krischtafowitch.—Glaciers in Russia, by H. Trautschold. Remarks against the glaciation of middle Russia, based upon the old conception of only mountain glaciers being able to produce glacial effects.—The *Olcostephanus nodiger* zone near Milkovo in Podolsk, government of Moscow, by D. Stremoukhoff. New species, *O. milkovensis*, described.—Note on some special cases of the problem of several bodies, by Th. Sloudsky.—Short report upon geological and botanical excursions in Yaroslav and Vologda, by Dr. Zickendrath.—On the neurokeratin, by Dr. J. Ogneff. This substance, in the sense established by Kühne and his followers, does not exist either in the peripheral nerves or in the brain; when obtained from the brain it represents a varied mixture of unsoluble remainders from the tissues composing the brain; the molecular substance (retina, brain) on the one side, and the neurokeratin-net in the peripheral nerves on the other side, cannot be considered as homological formations.—(*id.* No. 4). A list of the mammals and birds from the Aral steppes, by A. M. Nikolsky—New species, *Astragalus uralensis*, by Dr. Litvinov.—Note on the cold of January, 1893, by B. Sresnewskij.—To the memory of N. J. Kokscharoff and A. W. Gadolin, by V. Vernadsky.

SOCIETIES AND ACADEMIES.

LONDON.

Mathematical Society, June 8.—Mr. A. B. Basset, F.R.S., vice-president, in the chair.—The chairman announced that the Council had unanimously made the fourth award of its De-Morgan gold medal to Prof. F. Klein, of Göttingen, on the ground of his many contributions to the advance of mathematical science. The following communications were made:—Complex integers derived from $\theta^3 - 2 = 0$, and on the algebraical integers derived from an irreducible cubic equation, by Prof. G. B. Mathews.—Pseudo-elliptic integrals and their dynamical applications, by A. G. Greenhill, F.R.S. Writing the Elliptic Integral of the Third Kind in the canonical form—

$$I = \int \frac{Pz + nx}{(z + x)\sqrt{Z}} dz,$$

where

$$Z = 4z(z + x)^2 - \{(y + 1)z + xy\}^2,$$

then x and y are the quantities employed by Halphen in his "Fonctions Elliptiques," t. i. p. 103. Putting

$$z + x = \wp u - \wp v,$$

where

$$12\wp v = -(y + 1)^2 - 4x,$$

and

$$z_m + x = \wp mv - \wp v,$$

then

$$z_1 + x = 0,$$

$$z_2 + x = x,$$

$$z_3 + x = y,$$

$$z_4 + x = \frac{x(y - x)}{y^2},$$

and so on; and generally $z_m + x$ is the same as Abel's $\frac{1}{2}q_{m-1}$ if we replace Abel's x by $\frac{px}{4b^2}$, and $\frac{16b^3}{p^2}$ and $1 + \frac{4ab}{p}$ by Halphen's $-x$ and $-y$ (Abel's "Œuvres Complètes," t. ii. pp. 157, 163). Abel's recurring equation for q_m is now only another form of this elliptic function formula—

$$\wp(u + v) + \wp(u - v) = 2\wp v + \frac{\wp'^2 v}{(\wp u - \wp v)^2} + \frac{\wp'' v}{\wp u - \wp v},$$

with $u = (m - 1)v$; and the continued fraction expansion employed by Abel is not required, except, perhaps, for the determination of P. The integral I is *pseudo elliptic* when the parameter v is an aliquot part n of a period; and then

$$\mathrm{p}(n-1)v = \mathrm{p}v, \text{ or } \mathrm{p}(n-m)v = \mathrm{p}mv,$$

expressed by

$$z_{n-1} + x = 0,\ z_{n-1} = z_1,\ q_{n-2} = 0,$$

or

$$z_{n-m} = z_m,\ q_{n-m-2} = q_m.$$

The integral I can now, for odd values of n, be expressed in the form

$$2(z+x)^{\frac{1}{2}n} e^{\frac{1}{2}iI} = \{z^{\frac{1}{2}(n-3)} + Bz^{\frac{1}{2}(n-5)} + Cz^{\frac{1}{2}(n-7)} + \dots\}\sqrt{Z}$$
$$+ i\{Pz^{\frac{1}{2}(n-1)} + Qz^{\frac{1}{2}(n-1)} + Rz^{\frac{1}{2}(n-5)} + \dots\} = H\sqrt{Z} + iK,$$

where H and K are rational integral functions of z; the circular form of the integral being chosen on account of its dynamical applications. When n is even, a factor $z - a$ of Z can be inferred by forming $z^{\frac{1}{2}n} + x$; and then if $z - b$, $z - c$ denote the other factors of Z, the value of I can be expressed in the form

$$(z+x)^{\frac{1}{2}n} e^{\frac{1}{2}iI} = \{z^{\frac{1}{2}(n-2)} + Bz^{\frac{1}{2}(n-4)} + \dots\}\sqrt{\{(z-b)(z-c)}$$
$$+ i\{Pz^{\frac{1}{2}(n-2)} + Qz^{\frac{1}{2}(n-4)} + \dots\}\sqrt{(z-a)}.$$

The results for $n = 3, 5, 7, 9$ have been already given in the Proc. London Math. Society, vol. xxiv. pp. 7–10; thus for

$n = 3,\ x = 0$; $n = 4,\ y = 0$; $n = 5,\ y = x = -c$;
$n = 6,\ y = -c,\ x = -c(1+c)$;
$n = 7,\ y = -c(1+c), n = -c(1+c)^2$;
$n = 8,\ y = -c\dfrac{1+2c}{1+c},\ x = -c(1+2c)$;
$n = 9,\ y = -c(1+c)^2,\ x = -c(1+c)^2(1+c+c^2)$;
$n = 10,\ y = \dfrac{-c(1+c)}{(2+c)(1-c-c^2)},\ x = \dfrac{-c(1+c)}{(2+c)(1-c-c^2)^2}.$

But the next case of $n = 11$ presented difficulties, which were only overcome by the kind assistance of Dr. Robert Fricke, of Göttingen, and a reference to his article in the *Math. Annalen*, t. 40, p. 478. It was found that the relation

$$z_{11} + x = 0, \text{ or } z_5 = z_6,$$

equivalent to Halphen's $\gamma_{11} = 0$, or

$$(xy - x^2 - y^2)(y - x)^3 - xy(y - x - y^2)^3 = 0,$$

could be satisfied by

$$x = -c(1+c)(1+c+q),\quad y = -c(1+c) - \frac{cq}{1+c},$$

where

$$q(q+1) = c(1+c)^3,$$

or

$$1 + 2q = \sqrt{(1 + 4c + 8c^2 + 4c^3)}.$$

The relation between this c and the parameters τ and τ' employed by Klein and Fricke ("Modulfunctionen, t. ii. p. 440) or the parameters η and W employed by Dr. Kiepert (*Math. Ann.* t. xxxii. p. 96), was finally found to be

$$\frac{1 + 4c + 2c^2 - 5c^3 - 2c^4 + c^5}{c^2(1+c)^2} = \frac{1 - 10\tau + \tau'}{2\tau^2}$$
$$= \tfrac{1}{2}(\eta^2 + 6\eta - 16 + W).$$

Given τ and τ', or η and W, the five roots of the quintic in c will correspond to the five parameters,

$$(2, 4, 6, 8, 10)\frac{\omega}{11}.$$

Conversely, given c the values of

$$\mathrm{p}(2, 4, 6, 8, 10)\frac{\omega}{11}$$

can be found; as also the values of τ and τ', or η and W. According to Dr. Fricke's theory (*Math. Ann.* t. 40) the case of $n = 19$ should have a solution similar to that of $n = 11$. The general problem of the *pseudo-elliptic* integral is thus reduced to the determination of x and y, considered as the coordinates of a point on the curve

$$z_n + x = 0, \text{ or } z_{n-m} = z_m,$$

or

$$\gamma_n = 0 \text{ (Halphen)},$$

as functions of a parameter c; and when this is effected the values of $\mathrm{p}\dfrac{2s\omega}{n}$ can be found; and thence, in the manner of Kiepert, Klein, and Fricke, the various corresponding modular functions can be determined. In the dynamical applications to the motion of a top or gyrostat, the azimuth ψ can be divided into two parts, ψ_1 and ψ_2, where, according to the notation of Routh's "Rigid Dynamics,"

$$\psi_1 = \tfrac{1}{2}\frac{G + Cr}{A}\int\frac{dt}{1 + \cos\theta},\quad \psi_2 = \tfrac{1}{2}\frac{G - Cr}{A}\int\frac{dt}{1 - \cos\theta},$$

θ denoting the angular distance of the axis of the body from its highest position; and ψ_1, ψ_2 are thus two elliptic integrals of the third kind, having their poles at the lowest and highest positions of the axis, the positions of stable and unstable equilibrium. In ψ_1 we may put the parameter $a = p\omega_3$, where ω_3 denotes the imaginary half-period, and p is a proper fraction; also ψ_1 is pseudo-elliptic when $p = \dfrac{2r}{n}$, where r and n are integers. When n is an odd integer, the value of ψ_1 can be expressed in the form

$$(1 + \cos\theta)^{\frac{1}{2}n} e^{in(\psi_1 - p_1 t)} = H\sqrt{\Theta} + iK,$$

where H and K are rational integral functions of $\cos\theta$, of the degree $\frac{1}{2}(n-3)$ and $\frac{1}{2}(n-1)$, and

$$\Theta \text{ denotes } \sin\theta\frac{d\theta}{dt}.$$

But in ψ_2 the parameter is of the form

$$b = \omega_1 + q\omega_3,$$

where ω_1 is the real half-period; and to deduce a pseudo-elliptic expression for ψ_2 corresponding to $q = \dfrac{2r}{n}$, the factors of Θ must be known; say

$$\cos\theta - \cos\alpha,\ \cos\theta - \cos\beta,\ \cos\theta - \cosh\gamma,$$

α and β being the inclinations between which θ oscillates. Then, when ψ_2 is pseudo-elliptic,

$$(1 - \cos\theta)^{\frac{1}{2}n} e^{in(\psi_2 - p_2 t)} = H'\sqrt{\{(\cos\beta - \cos\theta)(\cos\theta - \cos\alpha)\}}$$
$$+ iK'\sqrt{(\cosh\gamma - \cos\theta)},$$

or

$$= H'\sqrt{\{(\cosh\gamma - \cos\theta)(\cos\theta - \cos\alpha)\}} + iK'\sqrt{(\cos\beta - \cos\theta)},$$

where H′ and K′ are rational integral functions of $\cos\theta$. By multiplication of these two equations for ψ_1 and ψ_2, we find an expression for

$$(\sin\theta)^n e^{in(\psi - pt)}$$

where $p = p_1 + p_2$; the values of the *secular terms* p_1 and p_2 being most readily determined by a differentiation and verification. Changing the sign of i in ψ_2, and denoting $\psi_1 - \psi_2$ by χ, $p_1 - p_2$ by q, we should find, as a verification,

$$(\sin\theta)^n e^{in(\chi - qt)} =$$
$$[L\sqrt{\{(\cos\beta - \cos\theta)(\cos\theta - \cos\alpha)\}} + iM\sqrt{(\cosh\gamma - \cos\theta)}]^n,$$

where L and M are constants, corresponding to an elliptic integral of the third kind, with a parameter

$$b - a = \omega_1.$$

The cases of $n = 3$ and 5 are worked out at length in the paper. The pseudo-elliptic expressions for ψ_2 are immediately available for the construction of *algebraical herpolhodes*, as the parameter in this mechanical problem is always of the form

$$\omega_1 + q\omega_3;$$

while the pseudo-elliptic expressions for ψ_1 can be utilised in the construction of solvable cases of the tortuous curve assumed by a revolving chain. In the herpolhode the case of $n = 3$ is realised when "the focal ellipse of the momental ellipsoid rolls on a plane at a distance from the centre equal to the difference of its semi-axes;" and when $n = 4$, "the distance of the fixed plane is equal to the distance from centre to focus of this focal ellipse." By Prof. Sylvester's theorems on correlated bodies, the motion of the bodies having momental ellipsoids confocal to this focal ellipse, can be inferred immediately. In the equations of the Precession and Nutation of the earth, or of the motion of an elongated projectile in an infinite frictionless liquid, the function Θ will be composed of four linear factors; so that in the construction of pseudo-elliptic algebraical cases of this motion, a return to Abel's original method may prove preferable, especially when n is an even number.—On the expansion of certain infinite products (II.), by Prof. J. L.

Rogers.—Note on some properties of Gauche cubics, by Mr. T. R. Lee. There are two principal theorems in the note, one being an analogue of the theorem of Desargues, and the other affording a test by which it may be determined whether a given line is a chord of a cubic or not.—Note on the centres of similitude of a triangle of constant form *circumscribed* to a given triangle, by Mr. J. Griffiths.

Physical Society, June 9.—Prof. J. Perry, F.R.S., Vice-President, in the chair.—Mr. A. P. Trotter read a paper on a new photometer. The author has modified his illumination photometer, described Proc. I.C.E., vol. cx. paper No. 2619, so as to adapt it to the measurement of candle-power. The principle employed is to view a screen illuminated by one source through an aperture in a second screen illuminated by the other light, the aperture becoming invisible when the illuminations are equal. After using perforations of various patterns, a series of narrow slits cut in thin paper were found to give the best result. The plain screen is mounted behind the slotted one in a box sliding on the photometer bench, and they are arranged so that the light falls on them at equal angles. The screens are viewed from a distance of 6 or 7 feet through an opening in the front of the box, cords being provided for producing the traversing motion. Two "sights" set respectively at the middle of the length of the plain screen, and on the lower edge of the front opening, serve to show when the middle of the band of equal illumination is vertically above the pointer on the carriage. The photometer is found to be particularly valuable when it is desired to determine the maximum power of a variable source. When lights of different colour are being compared—say a gas flame and an arc—one end of the screen shows blue strips on a yellow ground, and the other end yellow strips on a blue ground; at the centre the colours seem to blend. To facilitate the comparison of such lights, Mr. Crompton, who has been working at the subject simultaneously with the author, uses one screen tinted pale yellow and the other pale blue. Details of construction of the new photometer are given in the paper, and the accuracy attainable when comparing two equal lights of about eight candles, stated to be about 1 per cent.—Prof. S. P. Thompson, F.R.S., read some notes on photometry. The first note relates to the use of two overlapping screens as an isophotal, and describes the evolution of the Thompson-Starling photometer. In this instrument a prismatic block with apex upwards rests crosswise on the photometer bench, and the inclined sides are respectively illuminated by the two sources to be compared. In testing differently-coloured lights, coloured stuffs were placed over the surfaces of the wedge. In some cases notched and overlapping cards were used to form the overlapping surfaces; an inclination of about 70° between the two surfaces was found convenient. The second note refers to the periodic principle in photometry, and in it the author discusses the various methods which have been, or may be, used for producing small differences of decreasing amount between the two sides of a photometer screen. By employing a device of this kind much greater accuracy of adjustment is possible. In one form of vibration-photometer worked out by the author, the paraffin blocks of a Jolly's photometer are mounted at one end of a spring, the other end being fixed to the carriage. The act of moving the carriage starts the blocks vibrating, thus producing the desired variations. In a third note the question of using the electric arc as a standard of light is dealt with. Since 1878 the positive crater has been used as a standard of whiteness, and last year both the author and Mr. Swinburne suggested that a given area of crater might be used as a standard of light. This proposal has since been carried out by M. Blondel. Since the intrinsic brilliancy of the crater is high, it necessitates very small apertures, or else the use of standards of large candle-power. Advantages of using powerful standards are pointed out in the paper. With a circular hole 1 m/m in diameter, a standard of about fifty-five candles could be obtained; with such a source, benches longer than usual would be preferable. At the end of the note, the errors which may be introduced by using as an arc standard a hole in a plate of sensible thickness, when viewed obliquely, are investigated, as well as those due to inaccuracy of setting the plane of a hole made in foil, perpendicular to the photometer bench. Major-General Festing, in opening the discussion on both papers, said reflection from the sides of the hole in a thick plate would tend to lessen the error calculated by Prof. Thompson. The ordinary impurities in carbon were not likely to alter the brilliancy of the crater. Capt. Abney and himself had no reason to distrust its constancy. Both the vibrating photometer and Mr. Trotter's arrangement would be very useful.—Dr. Sumpner said his photometric experience had been obtained with the Bunsen, Jolly, and Lummer-Brodhun types. With the two former the inaccuracy arising from uncertainty of adjustment was about ½ per cent. Changes of about 0·4 per cent. (average) resulted from reversing the screens. The Lummer-Brodhun instrument (which he described) was better than either of the other two, the average error being about ¼ per cent. Mr. Frank Wright thought scientific men gave too little attention to the question of light standards. Photometers could be relied on much more than any standard at present in use. The Methven screen was the most practical standard yet devised, but in his opinion no gaseous flame could be a real standard on account of the influence of the surrounding atmosphere. Prof. Ayrton saw difficulties in using long benches as suggested by Dr. Thompson, on account of the serious atmospheric absorption which occurs with light from arcs. Decreasing the intensity by dispersion or otherwise was preferable. In some tests on glow lamps now being carried out at the Central Institution, a Bernstein lamp used as a standard was mounted on a spring and vibrated. Mr. Medley showed the vibrating standard referred to by Prof. Ayrton, and gave a series of numbers showing that with this device in conjunction with the Lummer-Brodhun photometer accuracies of about ¼ per cent. were obtainable. Mr. Swinburne thought Mr. Trotter's arrangement was better than the "wobbling" photometer. As to the best length of bench, he was inclined to think the shorter the better, provided its dimensions were large compared with those of the standard light. He concurred with Mr. Wright in his remarks about the desirability of obtaining a better standard. Speaking of the arc as a standard, he said that only impurities less volatile than carbon would influence the brightness. An important factor was the emmisivity of the carbon, which might not be constant. Mr. Blakesley thought the accuracy obtainable with Mr. Trotter's photometer had been underrated, and pointed out that by using quadrant-shaped screens intersecting orthogonally on the axis of the photometer instead of straight ones, the width of the neutral band could be greatly diminished. Mr. Trotter, referring to Dr. Thompson's paper, said he had found considerable difficulty in making pinholes suitable for arc standards. It was not an easy matter to accurately measure the hole when made. In photometric measurements he had found it very important to reverse his screens. Curved screens as suggested by Mr. Blakesley had been tried, but with little advantage. They also destroyed the approximate direct-reading property of the photometer. The subject of changing the length of a bench and its effect on the gradient of illumination was discussed. With short benches one had to guard against the departure from the inverse-square law, due to appreciable size of the standard. Recent experiments had shown that the light given out by 1 square m/m of crater surface differed considerably from 70 candles.—A paper on "The Magnetic Field close to the Surface of a Wire conveying an Electrical Current," by Prof. G. M. Minchin was taken as read. In this paper the author applies the solution he gave in March last for the conical angle subtended by a circle at any point in space to determine the magnetic potential at a point near the surface of a ring of wire of finite cross section. The shapes of the lines of force near the surface, for several laws of current distribution across the section, have also been worked out.

Chemical Society, May 18.—Dr. H. E. Armstrong, President, in the chair.—The following papers were read:—Studies on the formation of ozone (ii.), by W. A. Shenstone and M. Priest. Using an ozone generator of the Brodie pattern, the authors have studied the effect of discharges of varying difference of potential upon the quantity of ozone produced. The maximum proportion of ozone that can be produced at a given temperature is nearly independent of the potential difference employed, provided that this be within 33 and 69 C.G.S. units and that the path of the discharge be not very short at any point in the generator. When this latter case occurs the maximum quantity of ozone that can be obtained has an inverse relation to the difference of potential employed. The rapidity of ozonisation is greater with a high potential difference than with a low one, and the maximum proportion of ozone is produced with a low rate of discharge. A generator made of very thin glass, the two tubes of which fit rather closely, gives the greatest yield of ozone; for the same potential difference an induction coil ozonises a larger proportion of oxygen than either a Wimshurst or a Voss machine. The authors conclude from their experiments that the silent discharge acts by decomposing oxygen molecules into their atoms, which subsequently re-combine, to a greater or less extent, according to the conditions, to form the triatomic ozone molecules; it would hence seem that ozone is not formed by the direct action of the discharge.—The relative strengths or "avidities" of some compounds of weak acid character, by J. Shields. The author has calculated the relative strengths of a number of compounds of weak acid character, such as biboric and carbonic acids, hydrogen cyanide and phenol, from the rates at which salt solutions hydrolyse ethyl acetate.—The boiling points of homologous compounds. Part I.: Simple and mixed ethers, by J. Walker. The author finds that the boiling points of members of many homologous series may be very closely expressed by the relation $T = aM^b$, where T is the absolute boiling point, M the molecular weight, and a and b are constants peculiar to each series. The formula may be stated in the following form:—The logarithm of the ratio of the absolute boiling points of any two members of a homologous series, divided by the logarithm of the ratio of their molecular weights, is constant.—The conditions determinative of chemical change, by H. E. Armstrong.—The nature of depolarisers, by the same author.

Geological Society, June 7.—W. H. Hudleston, F.R.S., President, in the chair.—Dr. Johnston-Lavis, in referring to specimens and microscopic slides showing eozoonal structure in the ejected blocks of Monte Somma, exhibited by him, said that all the criticisms of *Eozoon* have so far been destructive, no analogous structure having been found in other localities under conditions that could explain the origin of so curious an arrangement of different minerals. These altered limestones from Monte Somma correspond in all details with those of the original Canadian specimens, and in many cases, on account of their freshness, exhibit some of the pseudo-organic structural details, such as the stolon-tubes, in far greater perfection than does the true so-called *Eozoon canadense*. He had been working at the subject in conjunction with Mr. J. W. Gregory. The following communications were read:—The bajocian of the Sherborne district: its relations to subjacent and superjacent deposits, by S. S. Buckman. This paper is partly the result of excavations made by Mr. Hudleston, F.R.S., and the author at Sherborne, to determine the position of the so-called "*Sowerbyi*-zone." The author used the term "bajocian" to denote the lower beds of what has been called "upper part of the inferior oolite." He introduced a term emar (ἡμαρ) as a chronological subdivision of an "age," and considered that the beds dealt with in the paper were deposited during 12 emata, which he called, in descending order, *fuscum zigzag*, *Truellii*, *Garantianum*, *niortense*, *Humphriesianum*, *Sauzei*, *Witchellia* sp., *discites*, *concavum*, *bradfordense*, and *Murchisonæ*. A line from Stoford, Somerset, through North Dorset to Milborne Wick, Somerset, is the base-line of the district reviewed. Seventeen sections of places close to this line were given to show the relations of the beds, with the different amounts of strata deposited during successive emata, and during the same emar at different places. By means of tables it was shown that the area of maximum accumulation receded eastwards in the earlier emata, and then proceeded westwards during the later emata. A similar and corresponding faunal recession and progression was pointed out, though the faunal headquarters always remain west of the great accumulation of deposit. Adding the various maximum deposits together, the author found as much as 130 feet of strata deposited during the twelve emata = (practically) the "Inferior Oolite of Dorset." This is a far greater thickness than had hitherto been allowed to beds of this age in the district, but the fault lay partly in incorrect correlation. The Dorset strata are correlated with strata in other districts—namely, with those of Dundry and Leckhampton Hills in this country. Of these the author gave sections, and pointed out the emata during which the strata of those localities were deposited, and made some alterations in their correlation. Passing to Württemberg, the author showed that the equivalent of Waagen's *Sowerbyi*-zone is exactly represented at Sherborne. Returning to Normandy, the results were compared with the recent work done by Munier-Chalmas, who in some respects has made an even more detailed subdivision of the strata. The corrrespondence between the divisions for Dorset and those of Munier-Chalmas in Normandy and Haug in Southern France was shown in a table. The President, Prof. Blake, the Rev. H. H. Winwood, and Mr. Marr took part in the discussion that followed.—On raised beaches and rolled stones at high levels in Jersey, by Dr. Andrew Dunlop. An account was given of the higher raised beaches examined by the author on the south-eastern and eastern coast, but probably found in other parts of the island also, as indicated by the existence of rolled stones, &c. These beaches seem to prove submergence (in the case of that at South Hill, to a depth of at least 130 feet below the present level) at the end of the "first glacier period." The brick clay often lying on raised beach, and containing pebbles, was compared to loess by the author. He believed that Prof. Prestwich's theory of sudden and rapid upheaval, with a resulting tumultuous sweep of water, may be applied to Jersey; but also, if the sinking took place at the end of the Glacial Period, the peculiar conditions produced by melting ice may have played their part in producing the brick-clays. Subsequent upheaval above the present sea-level is indicated by submerged forests, sometimes lying on the brick clay. No fossils have hitherto been found in the raised beaches; but a bone of *Bos primigenius* (?) has been extracted from the brick-clay. The President, the Rev. H. H. Winwood, and Mr. Monckton spoke on the subject of the paper.

Entomological Society, June 7.—Mr. H. J. Elwes, President, in the chair.—Mr. A. Cowper Field exhibited varieties of *Smerinthus tiliæ*, bred between 1890 and 1893, under varying conditions of temperature, those which had been exposed to a lower temperature being much darker than those which had been exposed to a higher. Mr. Merrifield made some observations on the subject, and remarked that, as far as his experience went, no hard and fast rule could be laid down with regard to the production of the lighter or darker colourings, as a high temperature sometimes produced dark forms.—Mr. W. M. Christy exhibited a series *Zygæna trifolii*, including very many yellow forms, all, with one exception taken at one spot during the latter half of May, 1893, and belonging to one colony. Some of the specimens were more or less incomplete, both in structure and colour, and Mr. Barrett stated as his opinion that this was due to their having been forced by the unusually fine weather. Lord Walsingham, Mr. Merrifield, and others took part in the discussion which followed.—The President remarked on the great abundance of *Coleophora laricella* in Gloucestershire, and stated that they were committing great ravages among young larches. Lord Walsingham stated that he had seen young larches at Carlsbad completely bleached by this moth.—It was suggested by several Fellows of the Society that care should be taken to observe the occurrence of second broods of insects during the year.—Mons. Wailly exhibited cocoons of various silk-producing Lepidoptera, and stated that the larva of *Attacus pernyi*, whose food-plant is oak, had been reared in Trinidad on *Terminalia latifolia*.

Linnean Society, June 15.—Prof. Stewart, President, in the chair.—Mr. A. W. Bennett exhibited some curious examples of revivification in plants, and made some remarks on the tentacles of *Drosera rotundifolia* and *longifolia*, specimens of which were exhibited under the microscope.—Dr. Stapf read a paper on the botany of Mount Kiua Balu, North Borneo, and exhibited some of the most characteristic plants. His remarks were criticised by Mr. W. T. Thiselton Dyer, who regarded the paper as a valuable contribution to geographical botany.—Prof. W. A. Herdman, in continuation of a former paper printed in the Society's journal, gave an interesting account of several species of British *Tunicata*, some of which were previously undescribed, his remarks being illustrated by figures projected on the screen by means of the oxy-hydrogen lantern.—On behalf of Miss A. L. Smith, Mr. George Murray gave an abstract of a paper on the anatomy of a plant brought from Senegambia by Mr. G. F. Scott Elliot, the affinities of which had not been precisely determined, but which was referred either to the *Melastomaceæ* or *Gentianaceæ*. The author's views, which were illustrated by means of the oxy-hydrogen lantern, were criticised by Dr. D. H. Scott.—In the absence of Mr. Scott Elliott, a paper was read on his behalf by the secretary, on the African species of the genus *Ficus*.—Prof. F. W. Oliver, on behalf of Miss M. Benson, gave an abstract of a paper entitled contributions to the embryology of the *Amentiferæ*, illustrated by diagrams of sections made by the author.—With this meeting the session of 1892–93 was brought to a close.

PARIS.

Academy of Sciences, June 12.—M. Lœwy in the chair.—Baron von Nordenskiöld was elected Foreign Associate.—On the theory of flow over weirs without lateral contraction, taking into account the variations undergone by the inferior contraction of the falling sheet according to the height of fall, by M. J. Boussinesq.—On the heat of combustion of the principal gaseous hydrocarbons, by MM. Berthelot and Matignon.—The differences of the heat of combustion in the homologues of the formene series are sensibly constant and amount to about 157.—On the modulus function $\chi\infty$, by M. A. Cayley.—Photographic study of some sources of light, by M. A. Crova.—Presentation of an iconographic monograph upon *Bubalus antiquus*, Duvernay, by M. A. Pomel.—On a class of surfaces with rational generators, by M. G. Humbert.—On some surfaces with several modes of generation, by M. G. Scheffers.—A general property of any field not admitting of a potential, by M. Vaschy. The distribution of the force (or vector) f at the various points of the field is identical with the distribution of the resultant of two fictitious forces f_1 and f_2 defined as follows:—The force f_1 would be developed by a system of masses acting at a distance according to the law of universal gravitation; f_2 would be developed by a system of "vectorial masses" acting according to Laplace's law. The density ρ of the first masses and the components μ_x, μ_y, μ_z, of the density μ of the vectorial masses would be given by

$$4\pi\rho = \frac{\partial X}{\partial x} + \frac{\partial Y}{\partial y} + \frac{\partial Z}{\partial z},$$

and equations of the type

$$4\pi\mu_x = \frac{\partial Y}{\partial z} - \frac{\partial Z}{\partial y},$$

where X, Y, Z, are the components of f, and the "vectorial mass" contained in an infinitely small volume $d\infty$ is $\mu\, d\infty$, where μ is the "density."—On terms of a superior order in the deviation of the compass, by M. E. Guyon.—On a remark of M. Guyon relative to the calculus of stability of vessels, by M. Ch. Doyère.—On the photographic properties of the salts of cobalt. Hydrated peroxide of cobalt dissolved in oxalic acid gives a solution of very unstable cobaltic oxalate, which is easily reduced to the cobaltous state by the action of light. This action may be utilised to produce photographic prints. A cobaltous salt is precipitated with sodium peroxide; the cobaltic hydrate formed is carefully washed in hot water, collected, and treated in the cold with a saturated solution of oxalic acid; the reaction, which must take place in the presence of an excess of cobaltic hydrate, is finished in several hours, and gives a green solution with which gelatinised paper may be impregnated. Printing is done very quickly. After sufficient exposure the proof is developed by means of a 5 per cent. solution of potassium ferricyanide, and fixed by simple washing. The image obtained is pale red. It is intensified and given a more agreeable colour by treating with an alkaline sulphide, which converts the ferricyanide of cobalt into the sulphide. The process is distinguished by its simplicity, rapidity and cheapness.—On Stas's atomic weights, by M. J. D. van der Plaats.—On chromodisulphuric, chromotrisulphuric, and chromosulphochromic acids, by M. A. Recoura.—Action of oxygen upon sodammonium and potassammonium, by M. A. Joannis.—On soft sulphur moistened in the state of vapour, by M. Jules Gal.—On the estimation of manganese by the oxydimetric methods, by M. Adolphe Carnot.—On the product of asymetry, by M. Ph. A. Guye.—On the alcoholic fermentation of Jerusalem artichokes under the influence of pure yeasts, by M. Lucien Lévy.—On a new series of colouring matters, by M. A. Trillat.—On the assimilation of the gaseous nitrogen of the atmosphere by microbes, by M. S. Winogradsky.—Observations thereon, by M. Berthelot.—On the doubling of carbonic acid under the influence of solar radiation, by M. A. Bach.—On *Micronereis variegata*, by M. Émile G. Racovitza.—On the oil of the eggs of the Algerian Pilgrim Cricket (*Acridium peregrinum*), by M. Raphael Dubois.—Influence of moisture on the development of the nodosities of the Leguminosæ, by M. Edmond Gain.—On the concordance of the phenomena of cellular division in the lilies and in Spirogyras, and on the identity of the causes producing them, by M. Ch. Degagny.—On the specific gravities of isomorphous crystals, by M. Georges Woulf.—On the axinite of Oisans, by MM. Albert Offret and Ferdinand Gonnard.—On the eruptive rocks of Servia, by M. J. M. Lugovic.—On *Polygonum sakhalinense*, regarded as fodder for cattle, by M. Doumet-Adanson.—On the toxicity of stereoisomeric acid tartrates, and a general formula for measuring their toxic power, by M. C. Chabrié.—The electric brush discharge as a treatment for refractory cutaneous pruritus, by M. H. Leloir.

ELECTRO DYNAMICS.

Dynamo Electric Machinery. Fourth Edition. Revised and enlarged. By Silvanus P. Thompson. (London: E. and F. N. Spon, 1892.)

A COMPARISON of the size of the fourth edition of this book with that of the first, which appeared in 1884, supplies a good illustration of the rate at which the use of dynamo electric machinery, and our knowledge of its laws, have advanced during the past eight years. The 408 pages in 1884 have grown to 832, with a collection of twenty-nine excellent plates in addition at the end of the book, representing another 60 pages; in fact, the book has now become so portly that it would have been well had the matter been put into two volumes.

Each of the last three editions has been bulkier than its predecessor, but the increase of size of the second and third represented the simple adding of new material without the pruning away of antique and practically obselete matter which is so necessary in a text-book of a rapidly advancing industry. The last edition, on the contrary, has been rewritten, and the author's well-known capacity for hard work and information collecting has enabled him to produce a treatise which contains the latest knowledge and the existing practice of the dynamo designer and the dynamo constructor of to-day.

The book opens with a wonderfully complete collection of historical notes, but we fear that the author's love of history has led him to give a little too much credit to the early workers. It is the fashion with some, and especially with those of classical tendencies, to credit the Chinese with the invention of gunpowder, the compass, and a variety of other useful commodities; to condemn Galileo, Columbus, and Harvey as plagiarists; and to extol Pliny or Aristotle, or other gentlemen of that somewhat remote period, as having foreseen and foretold every scientific principle and device.

But as these prophecies of the ancients were somewhat marred by their utter unsuggestiveness until the discoveries of the moderns had set the historian searching for a meaning which the writers of the prophecies were themselves probably quite ignorant of, we do not regard the trousered investigator as a dealer in second-hand articles.

Nobody knows better than Dr. Thompson that a knowledge of the properties of rubbed amber, or the discovery of the loadstone, was not all that was necessary to construct a 1000 horse-power dynamo with a commercial efficiency of 93 per cent., but nevertheless he fails, we think, to sufficiently distinguish between a chance mention of some notion and the subsequent independent recognition of an important commercial principle. If fame could really be achieved by a person's mingling a grain of wheat with a ton of chaff, what a temptation it would be to spend one's time recording every notion that struck one (no matter how improbable it looked), in the hopes that a hundred years hence some indulgent historian would search through the weary waste, in the hope of discovering with his rosy spectacles an apparent anticipation of some device that practice had then brought to a successful issue.

The historical notes are in fact not critical enough, and show a desire to make things comfortable all round for everybody. For example, the conventional illustration of the Pacinotti machine is given, but the author does not point out, indeed we do not remember to have seen it pointed out, that the original illustration of the Pacinotti generator differed from the conventional illustration in that the collecting-brushes were placed in the worst position, so as to make the machine as powerless as possible. May this have been the real reason why this machine "fell into temporary oblivion"?

If another example were wanted, we might take the following sentence, which, although not occurring in the section called "Historical Notes," enters as a note of an historical character on page 59, in the section, "Combinations to give Constant Pressure." The sentence is, "The combination of a permanent magnet with electro-magnets in one and the same machine is much older than the suggestions of either Deprez or Perry, having been described by Hjorth in 1854." Undoubtedly that is true, only Hjorth used the combination because, not being aware of the instability of the magnetism in a properly designed dynamo, he thought permanent magnetism was necessary to start the magnetic excitation; whereas Deprez and Perry superimposed what was practically a permanent field for a totally different reason and in a totally different way.

The chapters on "Magnetic Principles," the "Magnetic Circuit," "Forms of Field Magnets," are excellent. We do not, however, see much advantage in the introduction of what the author calls the *diacritical* current. The formulæ are thereby simplified, no doubt, but the simplification is effected at the sacrifice of accuracy; for first, the permanent magnetism in the field has to be ignored, and secondly, as there is no absolute maximum induction in iron, there can be no exact value of this *diacritical* current, which produces half the maximum induction.

The author is not quite happy in his choice of symbols. E is defined as representing the entire electro-motive force in the armature, e as the difference of potentials from terminal to terminal. Presumably, then, e_1, e_2, &c., applied to the separate coils of the armature, represent the potential differences at the terminals of the several coils. But that is exactly what e_1, e_2 do not mean, for they stand for the electro-motive forces of the coils. The suffix m attached to the letter for current or resistance denotes field magnet coils, but only when these are series coils. If the coils be shunt coils, the suffix s is attached to the letter. S, however, stands not for the number of shunt coils, as one would expect, but for the number of series coils, the former being called by a different letter altogether, viz., Z. In fact, Dr. Thompson's rules for the use of suffixes have the precision that is possessed by the rules for the spelling of the English language, the delight of every foreigner who studies them.

The description of "Combinations to give Constant Pressure" (pages 57, &c.), and of "Constant Potential Dynamos" (pages 277, &c.), might be well brought together, seeing that both parts of the book deal with the same contrivances, only a little mathematics is added when the subject is taken up the second time. The equations that are given were very useful in the early days when the combinations were first worked out, as they showed what combinations were theoretically possible to produce the desired result. But it is questionable whether these equations are of much use at the present time, or if they are given, it should be clearly explained why equations originally obtained on the assumption that the permeability of iron was constant led to conclusions distinctly valuable in the case of machines intended to produce constant pressure, but quite useless for suggesting a method of compounding a dynamo to produce constant current.

The chapter on lap, wave, and ring winding of armatures is most instructive. The original idea of cross connecting the coils of a gramme ring, so as to only require two brushes with a multipolar dynamo, the author attributes to Mr. Mordey, but we were always of opinion that Prof. Perry's patent of 1880 contained the first suggestion of this now well-known arrangement.

Chapters xiii., xiv., xv., xvi., xvii., and xviii., on "Practical Construction of Armatures," "Commutators, Brushes, and Brush Holders," "Mechanical Points in Design and Construction," "Elements of Dynamo Design," "Arc Lighting Dynamos," and "Examples of Modern Dynamos," taken in conjunction with the twenty-nine plates at the end of the book, contain a wonderfully compressed, and most admirable, *résumé* of British and foreign practice, and make one feel proud that they have been written by an Englishman.

In Chapter xx., on electromotors, the laws of maximum activity and maximum efficiency are carefully distinguished, and it is pointed out that, while Jacobi, Verdet, Müller, and even Weidemann stumbled, the true ideas of Thomson and Joule were put forth correctly by Achard in January 1879. In 1883 was advocated the proposal to employ a forward lead of the brushes with a motor, and a backward lead with a dynamo, so that the magnetisation of the armature might help instead of opposing that of the fields magnets. With reference to this idea the author says, "The fascinating notion of using the armature to magnetise has proved a failure in practice," a statement undoubtedly true historically, but lacking in prophetic inspiration, seeing that this proposal of May 1883, to utilise instead of counterbalancing the magnetism of the armature is now warmly welcomed in May 1893, after Mr. Sayers has shown how the "destructive sparking" can be annihilated.

Chapter xxii., on "The Principles of Alternate Currents," is much too meagre for any one who does not already know more of the subject than is contained in the chapter itself. A student reading the book would be inclined either to skip this chapter altogether and go on to the next, on "Alternators," or turn to some other book for what Chapter xxii. professes to give. The account of the construction of alternating current dynamos contained in Chapter xxiii. is as comprehensive as the description of the principles in the preceding chapter is meagre. The abstract of Dr. J. Hopkinson's investigation on the coupling of alternators is clearly given and easily understood, when the misprint of N A for N H on page 691 is corrected. The device of commutating the current round the field of an alternate current motor, so that when the motor synchronises the excitation is produced by a pulsating direct current, is due originally to Prof. Forbes, and not to Mr. Mordey, as the author states on page 702.

The author is very perplexing in his naming of alternating currents. He calls the current produced by an ordinary alternator a *two phase* current, but why we have no idea. At any one moment the current in all parts of the circuit is in *one phase;* at different times the current has, of course, every possible phase in succession. The current must therefore be called a *one phase* current, or a single current having every possible phase in succession, if the author prefers that; but there is no more reason to call such a current a *two phase* current than to call it a twenty-two phase current. When again we come to the arrangement devised by Ferraris, and illustrated in Fig. 455 (page 405), we have two distinct circuits, the currents in which always differ in phase. We have therefore a two phase arrangement. The author however calls this a "*four phase transmission.*" Lastly, however, when there are three circuits in which there are three distinct currents, the phases of which at any one moment are always all three different, the author, for some reason, is content to call this a "three phase current" like ordinary mortals.

Chapter xxv., on alternate and direct current transformers, is good, but might be made a little fuller, seeing that so very much work has been carried out on transformers during the past few years. The methods of testing transformers are becoming as important as those for "Testing Dynamos and Motors," which forms the subject of Chapter xxviii. The last chapter, on the "Management of Dynamos," contains many valuable hints, derived in some cases from the author's own experience.

The table at the end of the book, headed "Wire Gauge and Amperage Table," we have gazed at with feelings of admiration tempered with doubt. Admiration—because, if all the columns of numbers given in this table be correct, then, while we have spent much time experimenting and calculating in order to obtain information about the heating of one or two bobbins of wire traversed by a current, the problem for bobbins wound with all kinds of wire to all sorts of depths up to 4½ inches has in some way or other been solved. Doubt—because we fear that, in solving this problem, some sort of simple proportion may have taken the place of the complicated mathematics which it is necessary to employ on account of the flow of heat taking place across many layers of copper and cotton interspersed.

To say that this book is the best on its subject in the English language is to say too little, since we know of no book in any other language on the same subject that can be compared with it. The few peculiarities that we have drawn attention to must be regarded less in the light of blemishes than as giving the book individuality, for we recognise our best friends, when we meet them, by their characteristic peculiarities. Dr. Thompson's treatise should be, nay, probably is already, in the hands of every one who deals with dynamo machinery from an educational or from a manufacturing point of view.

It is interesting to notice how the author, in common with other writers, is unconsciously searching for a good abbreviation for the important, but somewhat cumbersome, expression—difference of potentials. Sometimes he calls it pressure, but he apologises for that, as he says it is popular. Sometimes he calls it potential, which we think is rather the expression to be apologised for, since it is wrong, the potential of a body having years ago been defined as being the difference between its potential and that of the earth. Sometimes he calls it the volts, but to speak of the volts of a dynamo being too high is like telling your tailor that a coat has too many inches when you mean it is too long. Voltage again appears to us as bad as amperage, a name which, by the bye, enters into the heading of the last table in the book. If we talk of the amperage instead of the value of the current in amperes, why not speak of the microfaradage of a condenser instead of its capacity in microfarads, or of the feetage of a tall man as being 6½? The names current, resistance, capacity, &c., require a short analogous name for difference of potential. Years ago Mr. Latimer Clark suggested that the name *potency* was going a-begging. How would this do as short for potential difference if the industrial name, pressure, be objected to? But, the shortest abbreviation of all is the initials of the words potential difference and our own, P. D.

CAPTAIN COOK'S JOURNAL.

Captain Cook's Journal during his First Voyage round the World, made in H.M. Bark "Endeavour," 1768–1781. A literal transcription of the original MSS., with notes and introduction. Edited by Captain W. J. L. Wharton, R.N., F.R.S., Hydrographer of the Admiralty. Illustrated by maps and facsimiles. (London: Elliot Stock, 62, Paternoster Row, 1893.)

CAPTAIN WHARTON has rendered excellent service to naval and colonial history, and to geographical science, by editing a transcript of Captain Cook's journal of the voyage of the *Endeavour*, which was undertaken chiefly for the purpose of observing the transit of Venus across the sun's disk, and which led to the founding of the Australian Colonies by Great Britain. As is well known, the published accounts of that voyage are two, and neither of them satisfactory. The only very complete one is that compiled by Dr. Hawkesworth, from the journals of Cook, and of Mr. (afterwards Sir Joseph) Banks, who accompanied the great navigator as a volunteer, taking with him an eminent scientific man, Dr. Solander, a pupil of Linné, two artists, and servants, all of his own providing. The other is a brief and defective journal kept by Mr. Parkinson, one of Banks's artists, who died before the expedition reached England. It contains rude illustrations of the scenery and peoples of the Pacific Islands, which, if faithful reproductions of the originals (which I doubt), would show that his artistic powers were contemptible. Parkinson's narrative, which was edited by his brother, was published surreptitiously. It was suppressed by authority, and is, happily, not frequently met with.

Dr. Hawkesworth, on the other hand, has been severely and justly censured for the method he adopted, namely, the fusion of the journals of Cook and Banks,[1] and for attributing to their authors inept reflections of his own, an operation for which, even had it been advisable, he had not the ability, from his obvious want of appreciation of the distinctive labours of the navigator and of the naturalist." The result is a narrative in which the performances of the actors are inextricably confounded, and the records of Cook, and doubtless also of Banks, in some cases garbled. With regard to the reflections, they are comparatively of small account, and there is little difficulty in recognising and rejecting them; they were in keeping with much of the literary style of the age, and Dr. Hawkesworth assures the reader that his whole work was before publication submitted to and approved by the members of the expedition then in England.

Unsatisfactory as Hawkesworth's account of the voyage is, it has the inestimable advantage of in some measure filling what would otherwise be a lamentable void in the annals of science, for strange as it must appear, not even a meagre life of Banks has ever been written, and but for Hawkesworth's work and "Cook's Journal," there is no published account of his indefatigable labours during the expedition. Banks, no doubt aided by Solander, kept a full journal of many events that happened during the voyage, which the commander had not the opportunity of witnessing or recording; and the admirable observations on the physical features, populations, languages, economic products, manufactures, zoology, and botany, of the islands, and coasts visited, are presumably for the most part his. Cook, indeed, especially mentions the signal services which Banks rendered, especially in the management of the natives, in acquiring their languages, in provisioning the ships, and in collecting information and objects of interest; and it needs no reading between the lines of his concise narrative to prove his appreciation of his companion, who he invariably took with him wherever he landed.

The materials for the reproduction of the journal of which Captain Wharton has availed himself with great judgment, are a complete copy of "Cook's Journal" in the possession of the Admiralty; another belonging to the Queen, that was transmitted to England from Batavia, thus containing everything of importance; and thirdly, a duplicate of this last, which having been appropriated by the Secretary of the Admiralty, Sir Philip Stephens, passed to his descendants, and from them by sale first to Mr. Cosens in 1868, and in 1890 to Mr. John Corner. The latter gentleman was arranging for the publication of his copy, with the view of devoting the proceeds to the restoration of Hinderwell Church, the parish church of Staithes, whence Cook ran away to sea, when he suddenly died, and the carrying out of his project devolved upon his son, who completed the arrangements which led to Captain Wharton's under-

[1] Sometimes alluded to as the journals of Mr. Banks and of Dr. Solander, though there is no reason to suppose that the latter individual kept any journal independently of that of Banks, of whom he was probably the amanuensis, as Mr. Orton (the ship's clerk) was of Cook.

[2] A conspicuous example of this is Hawkesworth's omission of the passage in Cook's journal (Wharton, p. 322) dwelling on the unaccountable absence of the cocoa-nut (except of its shells cast upon the beach) on the east coast of Australia, which is a most remarkable feature in the geographical distribution of that plant. A few living specimens exist at Rockhampton and Keppel Bay, but in an unhealthy state, producing no fruit, and probably introduced by Europeans.

taking the editorship. The latter informs the reader that the text is from Mr. Corner's copy, so far as it goes, with additional matter, from the date of the arrival at Batavia up to reaching England, from the Admiralty copy.

In an interesting chapter of fifty pages Captain Wharton gives a spirited sketch of Cook's life and labours from his birth in 1728 to his murder in 1779. It contains a list of the antiscorbutics supplied to the *Endeavour*, and an account of the preventive measures adopted to ward off sickness in his ship. It is not mentioned in it that this led to his election, after his return from his second voyage, to the Fellowship of the Royal Society; before which Society he communicated a paper on the above measures, and another on the tides along the east coast of New Holland. Nor that for the former of these he was awarded the Copley medal by the President and Council, the highest honour in the gift of any scientific body, and the more honourable in the case of Cook, from the fact of the medal having been instituted as an award for discoveries or researches in experimental science. It is a melancholy fact that Cook's departure on his third voyage prevented his receiving in person this the sole public recognition of his still unparalleled services.

To dwell upon Cook's professional labours would be out of place here, are they not written in his own Report? which is a model of completeness and conciseness, recalling in these respects the Wellington despatches. There is a reason for the minutest detail, down to the naming of islands, bays, straits, and inlets, with the result of these being as appropriate as are Linné's names of animals and plants.

Captain Wharton has further illustrated his work with valuable footnotes and facsimiles of some of Cook's original charts, as of the Society Islands and New Zealand, making that of the Australian coasts specially interesting by placing on the same sheets parallel with Cook's chart of 1770 one corrected up to 1890, and reduced to the same scale, thus showing the marvellous approximate accuracy of the former. It is to be regretted that no list of the charts and plates is appended to that of the chapters into which, for convenience, Captain Wharton has divided the Report. It is difficult to find some of these in a work printed on thick paper with uncut edges; and without such a list there is no assurance that a copy is perfect.

In the preface, Captain Wharton says (p. vii) "that it has several times been in contemplation to publish Mr. (afterwards Sir Joseph) Banks' Journal, but this has never been accomplished," and again (p. xxvi) that the said Journal "cannot at the present time be traced." This was, till the other day, true. Captain Wharton had spared no trouble in his endeavours to trace it; and the writer of this notice had, at intervals, for many years past pursued the same object, he having a personal interest in its discovery, as being one of the few persons living who had seen it. Its history he believes to be the following. On Sir Joseph Banks' death, without issue, in 1820, his effects passed to the Knatchbull family, with the exception of his extensive Herbarium, Library, and the lease of his house in Soho Square, which were left to the late eminent botanist, Mr. Robert Brown, who had been for many years Banks' librarian, with the proviso that the Herbarium and Library were to be eventually deposited in the British Museum. The Banksian correspondence and papers, including the Report, were thereupon confided to Mr. Brown, with the object of his writing a Life of Banks. Age and infirmities interfered with the prosecution of the work; and the materials were for the same object transferred, in the year 1833, to my maternal grandfather, Mr. Dawson Turner, F.R.S., a naturalist, and man of high literary attainments, in whose house I aided in the collation of a copy of the Journal, which he had caused to be made, with the original. In Mr. Turner's case they met the same fate as in Mr. Brown's, and they were then placed in the hands of the late Prof. Thomas Bell, secretary of the Royal Society, and who succeeded Brown as President of the Linnæan, in the hope that he would undertake a Life of Banks. After retaining the materials for some time he declined the task, but before returning them (in 1857 or 1858) he submitted them to Mr. John Ball, F.R.S., who also declined. Nothing further was known to me or to Captain Wharton of their history until last week, when (having previously been misinformed on this point) I ascertained that the original of all Banks' correspondence and of his Journal of the *Endeavour's* voyage, were in the MS. Department of the British Museum, and the aforesaid copy in the Natural History Department of the same Institution. It only remains to add the hope that this gratifying intelligence may lead to the publication of Banks' Report uniformly with Captain Wharton's admirable edition of Cook's.

J. D. HOOKER.

OUR BOOK SHELF.

The Soil in Relation to Health. By H. A. Miers, M.A., F.G.S., F.C.S., and R. Crosskey, M.A., D.P.H. (London: Macmillan and Co., 1893.)

THE attractive title of this little book speaks for itself, indicating that it is one of those numerous endeavours which are being made at the present day to supply just such an amount of information in several different sciences as will satisfy the requirements of men engaged in some particular department of practical life. In the present case it is a combination of chemistry, geology, and bacteriology which is offered for the benefit of the sanitary officer. The task undertaken by the authors is obviously a difficult one, and, if the book be regarded as a mere outline stimulating the reader to more extended and special study, they may be said to have accomplished this task with a fair degree of success. Our knowledge of the chemical and biological changes taking place in the soil has, during recent years, been so much increased, and is in some respects so complete, that it might have been anticipated that much of this book would have been devoted to a clear exposition of such matters as nitrification and denitrification, the micro-organisms of water, their removal by filtration and other agencies, the purification of sewage, &c. As a matter of fact, the account given of nitrification is incomplete, whilst of the other subjects referred to above, and which are of such cardinal importance in connection with sanitary science, we find hardly any mention whatsoever. On the other hand, there are long passages devoted to such speculative matters as the causes of epidemic infantile diarrhœa, the connection between typhoid and the depression of ground-water, the relationship between soil and the prevalence of cancer and phthisis, &c. In the chapter on water-supply we are informed that the water from the magnesian limestone is "too permanently hard to be a wholesome drinking-water," whilst a few lines further on we are surprised to read that "the total solids rarely exceed 20 grains per gallon." The chapter on the atmosphere makes no mention of the numerous investigations which have been made both at home and abroad on the aërial microbes and their distribution. The authors almost apologise for the prominence they have given to the subject of micro-organisms, but we think they might more appropriately have tendered some excuse for their unfortunate frontispiece, which endeavours to represent the microscopic appearance of the typhoid and anthrax bacilli; for whatever the excellence of the original illustrations may have been, the reproductions in the copy before us do little credit to British printing.

Practical Astronomy. By P. S. Michie and F. S. Harlow. Second edition. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1893.)

IN this book the authors have brought together all those astronomical problems which are required for field work, limiting themselves simply to these, and dealing with them at sufficient length for practical work. The volume is intended especially for the use of cadets of the U.S. Military Academy, and as a supplement to Prof. Young's text-book, and several subjects not sufficiently discussed there for this special branch of practical work are here expanded. After a short discussion on the uses of the *American Ephemeris and Nautical Almanac*, and a few words on interpolation, the authors launch out into the usual methods of determining Time, Latitude, and Longitude on Land, explaining them concisely and deducing the requisite reductions formulæ. Corrections for refraction, parallax, &c., also receive a good share in their respective places, while the instrumental errors are fully explained and discussed. Excellent illustrations of instruments (those in use in the Field and Permanent Observatories of the Military Academy during the summer encampment) are inserted and described. In addition to a set of tables collected together at the end, a few well-arranged forms, showing the methods of computing several problems, are inserted, which should prove a great help to those not accustomed to such calculations.

W. J. L.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Publication of Physical Papers.

THERE is little doubt that there is much to be done towards improving the machinery connected with the publication of papers on physical science. By publication of a paper I do not mean printing and binding and sending it to libraries in inconvenient places, which are open at inconvenient hours, but bringing it under the eyes of those interested in its subject. It is hardly possible to discuss this matter without being personal to journals and societies, so perhaps direct references may be allowed.

The present position is that as societies we have the Royal Society, which nominally embraces all branches of science, and the Physical Society, which is alone devoted entirely to physics, and several important general scientific societies scattered about the present kingdom. We have also some journals. Of these NATURE must here be put first, but NATURE is by no means purely physical, and is a scientific newspaper, and not a collection of scientific papers, and, owing to the nature of the case, incomplete as regards abstracts. The *Philosophical Magazine*, with its splendid record, fills its place alone. It contains a certain proportion of original papers, and a number of others communicated by the Physical Society, with which there is evidently an arrangement. There are also purely electrical paper like the *Electrician*, which covers most branches of electrical work, and the *Electrical Review*, which publishes filtrates of papers on electrolysis and kindred subjects editorially, with the names and references left out; an annoying proceeding. Coming to the societies, the Physical Society is alone devoted to physics. The Royal Physical Society in Edinburgh need not be considered, as it indulges in ornithology and things of that sort. The Physical Society publishes well. Abstracts of the papers and discussions appear in NATURE and in most scientific or technical, and in some literary journals. The papers are often published in the *Philosophical Magazine*, and again in the Society's own Proceedings. No doubt in time this society will be to physics as the Chemical is to theoretical chemistry, but at present it does not command by any means all the most important physical papers. There is also some waste in republishing in the *Philosophical Magazine* and the Proceedings, though this does not cost much. The arrangement with the *Philosophical Magazine* prevents the immediate publication of a Physical Society paper in the scientific and technical journals at home and abroad. This is a source of weakness. A society which objects to its papers being published everywhere before appearing in its own journal does much to defeat its own ends. The Physical may be unable to help this, but in the Royal, or other wealthy institution, it is defeating the main object of the society's existence for the sake of selling a few odd copies of the Proceedings. To go back to the Physical, the result is that its papers are never reprinted either from the *Philosophical Magazine* or from the Proceedings. The *Philosophical Magazine* is not very cheap, and the Proceedings are, I think, not sold to non-members.

The Royal Society gets physical papers. I believe they are sometimes read, but do not know, not being a Fellow. The best papers are published a long time afterwards in a form which is very expensive to buy, and those who are not Fellows generally know nothing about them until they find them by chance. Royal Society papers, again, are seldom reprinted in the journals.

Then there are various other societies, like the Royal Society of Edinburgh, and the Cambridge and Dublin societies, which shroud valuable papers of all sorts in their transactions, and bury them in public libraries. The result of the present state of things is that an English physicist—it is difficult to get on without this curious word—has no simple means of following the progress of his own special study.

There are several courses which would improve matters, but none of these is perfect. The most obvious is for all physical papers of any importance to be sent to the Physical Society, and published in its Proceedings. The advantages of this need hardly be enumerated. Of course the Physical Society would develop, and would at once become one of the most important in the world. The drawback is that if this principle were carried out in all branches of science we should have a number of special societies in London, and none anywhere else, which would be a very bad arrangement. Another plan would be for the various societies to join, so that one journal, say that of the Physical Society, contained all the important physical papers read at the various societies. A society would communicate its best papers to the Physical Society's Proceedings, these Proceedings being controlled partly by representatives of all the other societies. The papers would, of course, also appear in the Proceedings of the societies to which they really belonged. One drawback to this would be that the Royal Society might object to communicating its papers to the Physical; and this might lead to competition between a special and a more powerful general society.

Another course would be for the Royal Society to act as the central body. This would be rather hard on the Physical, and would tend to reduce its standing, so that we would have no first-rate society devoted specially to physics in a country where an enormous amount of work is done in a disorganised way. There would be another difficulty. The Royal Society standard of papers is supposed to be very high, and though it occasionally publishes papers of no value, the high standard generally maintained would exclude many papers of great importance which were hardly good enough for the Royal Society. Then the Royal Society is specially devoted to pure—that is unapplied science, and there are very many papers on applied physics which are of the highest importance.

Still another course would be for a firm of publishers to bring out a purely physical paper. The stumbling-block here is the question of advertisements. According to Mr. Thiselton Dyer, scientific men are supposed to beunbusiness-like, no doubt without reason; but it may be well to remind them that most journals live on their advertisements, the reading matter being a necessary evil. It would thus be commercially impossible to run a purely physical paper, as there is no trade, except to a certain extent electrical engineering, which has much to do with physics.

It might be better to abandon the idea of a central organ for physics, and to publish a complete set of abstracts. Abstracts to be useful must be very well made, and they must be complete. It is very difficult to get good abstracts. The work is laborious and costly when efficiently done. Abstracts are only a developed index, and it would still be necessary that separate papers should be obtainable. Incomplete abstracting is a very common vice. It is not enough to have a few papers brought under a reader's notice: that is good when one is reading for general information in an indolent way, but it is useless in the far more common case in which he wants to know either all that has been done on a given subject, or whether some discovery has been hit upon before. A scientifically worked out subject index is also essential, and, as said before, the abstracts must be practically complete. JAMES SWINBURNE.

4, Hatherley Road, Kew Gardens, June 25.

The Glacier Theory of Alpine Lakes.

I HAVE read with interest the discussion in NATURE on the "Glacier Theory of Alpine Lakes," and I feel constrained to write now, more especially as Mr. Wallace has cited Tasmania as a country, among others, where Alpine lakes are associated with "palpable signs of glaciation." Having recently, with Prof. Spencer, of Melbourne University, made a visit to the central lake district of Tasmania, a few words about the lakes may not be without interest in reference to the subject under discussion.

The lake district of Tasmania is situated about the centre of the island on the great central greenstone plateau, which attains to a height of 4000 ft. above sea level in places. We camped on the shores of Lake St. Clair, and remained there during the whole month of January of this year. Lake St. Clair is about 2500 ft. above the sea, and is about 11 miles long by 2 broad. It occupies a narrow valley between the Olympus Range on the one hand and the Traveller Range on the other. A depth of 590 ft. is recorded. Its basin probably lies in sandstone (carboniferous?), the structure of the adjoining mountains being sandstone capped by greenstone (diabase).

Both Prof. Spencer and myself, being believers in the glacier theory of Alpine lakes, had half expected to find evidences of glaciation, especially as we had heard of well marked signs being found on the west coast, some 50 or 60 miles to the northwest. However, we could not find the slightest trace of glacial action. From the top of Mount Olympus, rising about 2350 ft. above the surface of the lake, we got a magnificent view of the country. The Traveller Range opposite is really the edge of a great greenstone plateau, stretching away with a roughly undulating surface for miles beyond. The surface of this plateau is studded all over with lakes and tarns of various sizes and at different levels. In other directions, too, lakes can be seen here and there nestling in the valleys. In all we counted between thirty and forty lakes and tarns from the top of Mount Olympus. Two small basins of water—the "Olympian Tarns"—rest on the flanks of the mountain itself. On the opposite side of Olympus from St. Clair lies Lake Petrarch, occupying an oval basin and apparently of shallow depth. This lake is about 560 ft. above St. Clair. On the right shore of St. Clair occurs another small lake (Lake Laura) 50 ft. above the former, and separated from it by a ridge about 3400 yards across.

A characteristic feature of this district are the "button-grass" flats. These are open, marshy expanses covered with "button-grass" (*Gymnoschœnus sphærocephalus*) and other plants. They are traversed by numerous little runlets of water, which usually unite into one or more main streams. Here and there in many of them masses of greenstone protrude. Between these "flats" are generally low ridges of greenstone covered with Eucalyptus and Banksias, &c. Many of these flats or marshes—as, for instance, those in the Cuvier Valley, at the head of which lies Lake Petrarch—reminded me very strongly of the moorland scenery in the Scottish Highlands, and the plateau, already referred to, with the lakes and tarns scattered over its surface, might be a scene in Sutherlandshire. But in all our wanderings we did not find the slightest sign of glaciation either in the form of moraines or of striated rock-surfaces. We were not able to examine the lakes on the plateau mentioned, but from its configuration I am confident that evidences of glaciation do not exist. On the west coast, notably about the Pieman River, signs of glaciation are, I believe, abundant, and numerous tarns and rock basins are associated with them. Here the neighbouring mountains are not so high as those further inland, and it was probably their proximity to the coast that was the cause, during the last glacial epoch, of glaciers being formed there and not further inland.

So then, though in Tasmania there are instances of rock-basin lakes being associated with undoubted evidences of glaciation, yet, as I have shown, the glacier theory will not account for by far the greater number of the Alpine lakes on the great central greenstone plateau. I do not propose to put forth any theory to account for these lake-basins, but have put down the above facts in the hope that they may prove of some interest in the question at issue, and to show that at least there are some exceptions to Mr. Wallace's statement that Alpine lakes only exist in glaciated regions.

I may add that Lake St. Clair has been accounted for by Gould, who explained it by supposing that a flow of basalt had dammed up the lower end of the valley in which the lake lies. I am, however, much inclined to doubt the existence of this basalt. Though we traversed the end of the lake where it is said to occur, we did not recognise any basalt.

It may also be remarked about the "button grass" flats or swamps, that they really occupy rock-basins, and may perhaps be regarded as the analogues of the peat-bogs of Scotland and Ireland. All those occurring in the same drainage area seem to be directly connected with each other, and I think there can be little doubt that many of them were formerly occupied by lakes.

Melbourne University, May 7. GRAHAM OFFICER.

THE Editor having given me the opportunity of reading Mr. Graham Officer's interesting letter, I will make a few remarks upon it.

It seems to me that, without further information as to the nature of the search for drift, erratics, or ice-worn surfaces, and judging from the statement that the plateau studded with lakes and tarns was only looked down upon from an adjacent mountain summit, we can hardly give much weight to the positive statements, "I am confident that evidences of glaciation do not exist," and—"as I have shown, the glacier theory will not account for by far the greater number of the Alpine lakes on the great central greenstone plateau." Some light may perhaps be thrown on the matter by the consideration that the undoubted marks of glaciation in many parts of Australia are believed to have been caused by, comparatively, very ancient glaciers, since some of the glaciated surfaces are overlain by pliocene deposits, while others are believed to be of palæozoic age. If the Tasmanian glaciation was also of pliocene age, most of the superficial indications may have been destroyed by denudation, or, if preserved, may be hidden by vegetation or by alluvial deposits. We must therefore wait for a much more thorough examination of the district and of other parts of Alpine Tasmania before it can be positively stated that no evidences of glaciation exist.

ALFRED R. WALLACE.

Vectors and Quaternions.

I WOULD like to ask Prof. Knott whether there would be any fatal objection to defining the scalar product of two vectors as equal to the product of their tensors into the cosine of the angle between them, so that, if the vectors are

$$ix_1 + jy_1 + kz_1,$$

and

$$ix_2 + jy_2 + kz_2,$$

the scalar product would be

$$x_1 x_2 + y_1 y_2 + z_1 z_2,$$

and not

$$ix_1 . ix_2 + jy_1 . jy_2 + kz_1 . kz_2.$$

If this is done, and, for the sake of associativeness of products, i^2 is made equal to -1, the distributive or quaternionic product of two (or more) vectors would be their vector product *minus* their scalar product. The change suggested would enable students to gradually accustom themselves to the notation of the calculus, which would in fact then form an abridged notation for the cartesian expressions and operations which enter into physical investigations.

I would ask Prof. Knott to give this suggestion his careful consideration, as I am sanguine enough to believe that in it, simple as it appears, lies the possible reconcilement of the new school of vector analysts with the quaternionists. Possibly some symbol other than S would have, at any rate at first, to be employed for this new scalar product. Perhaps, with Prof. Macfarlane, it might be called the cos-product, though that notation properly belongs to the scalar product of two vectors only, and loses its significance if applied to the scalar product of three or more vectors. No single letter symbol could be better than S, as it is distinctive and quick to write. However, the first question is whether there is any possibility of the modification being adopted.

The quaternionic product of a vector by itself would be minus its scalar square, but without any mystery attached to the fact. For the product of two vectors = vector product − scalar product, and therefore, if the vector product is zero, the quaternionic product = − the scalar product. Hence, instead of having

$$(\alpha + \beta)^2 = \alpha^2 + 2S\alpha\beta + \beta^2,$$

we should have

$$S(\alpha + \beta)^2 = S(\alpha^2 + 2\alpha\beta + \beta^2).$$

Reciprocal vectors satisfy the equation $\beta^{-1}\beta = 1$, so that $S\beta^{-1}\beta = -1$, *i.e.* β^{-1}, β are oppositely directed vectors.

The quaternion

$$\alpha\beta^{-1} = \frac{\alpha\beta}{\beta^2} = \frac{V\alpha\beta - S\alpha\beta}{-S\beta^2} = -\frac{V\alpha\beta}{S\beta^2} + \frac{S\alpha\beta}{S\beta^2},$$

showing clearly that both the vector and scalar products of $\alpha\beta^{-1}$ are opposite in sign to those of $\alpha\beta$, as must, of course, be the case since β^{-1} and β are oppositely directed vectors. This fact is obscured with the orthodox notation. In fact, so far as I have been able to test the proposed change, I have found no drawbacks, but rather an improvement. ALFRED LODGE.

Sagacity in Horses.

FROM the window opposite, as I write, I have just witnessed an interesting performance on the part of two horses. Bordering the park is a strip of land, doomed to be built upon, but meanwhile lying waste, and used for common pasturage, on which the horses under notice were leisurely grazing. A pony in a cart, having been unwisely left by the owner for a time unattended on the grass, suddenly started off, galloping over the uneven ground at the risk of overturning the cart. The two horses, upon seeing this, immediately joined in pursuit with evident zest. My first supposition, that they were merely joining in the escapade in a frolicsome spirit, was at once disproved by the methodical and business-like manner of their procedure. They soon reached the runaway, by this time on the road, one on one side of the cart, and one the other; then, by regulating their pace, they cleverly contrived to intercept his progress by gradually coming together in advance of him, thus stopping him immediately in the triangular corner they formed. Until the man came up to the pony's head they remained standing thus together quite still; when the two horses, evidently satisfied that all was now right, without any fuss trotted back again together to their grass.

The sagacious conduct of the horses, acting in such perfect cooperation, formed a pretty sight; and it was apparent that, instead of making the pony more excited, they really pacified and calmed him. Why should they not receive "honourable mention" as much as if they were proud human beings?

WILLIAM WHITE.

The Ruskin Museum, Sheffield, June 20.

TERCENTENARY OF THE ADMISSION OF WILLIAM HARVEY TO GONVILLE AND CAIUS COLLEGE, CAMBRIDGE.

BORN at Folkestone, and educated at the King's School, Canterbury, William Harvey was admitted to Gonville and Caius College as a minor scholar in his sixteenth year, on May 31, 1593. The tercentenary of this event was celebrated by Harvey's College on Wednesday, June 21, this being the earliest day after the date of his admission at which rooms were available for those coming from a distance. The guests were received and welcomed by the Master and Fellows, at five o'clock, in the large Combination Room, where tea was provided. In the smaller adjacent room were exhibited a number of objects of interest connected with Harvey, including his pestle and mortar, from the Museum at Folkestone, a rubbing from his mother's tomb, an autograph letter of Harvey, lent by the Master of Sidney Sussex College, and a coloured drawing of Harvey's coat-of-arms, recently discovered on the walls of the buildings of the University of Padua. The latter was presented to the College by the University of Padua, followed on the day of the festivity by a long congratulatory Latin telegram from the Rector, on behalf of the University, which ran as follows:—"Universitatis Patavinæ quæ cum aliis Britannis discipulis tum Harveio Caioque gloriatur, quorum alterius merita insigne Collegium vestrum nunc recolit nomenque ex altero invenit, festi in Harveii honorem indicti participem se profitetur et in renovanda cum celeberrima Universitate Cantabrigiensi vetere studiorum amicitiæque memoria summopere lætatur, pro Academico Senatu, Ferraris Rector." Also an autotype of the panel-portrait of Harvey from Rolls Park, Chigwell, Essex, presented to the College by Sir Andrew Clark, as one of a series of eight, consisting of a central portrait of Harvey's father, surrounded by those of his seven sons. Some early editions of the works of Harvey and of some of his more immediate predecessors and followers were also displayed, together with the admission book of the College, containing the original record of his admission. At seven o'clock the guests assembled once more in the Combination Room, whence they proceeded to dinner in the College Hall, led by the butler, bearing the original "caduceus," as used by Dr. Caius when President of the College of Physicians. The dinner was presided over by the Master of Gonville and Caius College, the Rev. N. M. Ferrers, D.D., F.R.S., above whose chair were displayed a copy of the bust from the Harvey Memorial, crowned with a laurel wreath, and the much-prized portrait of Harvey from the Master's Lodge. After dinner the Grace Anthem of the College, composed by Mr. C. Wood, was sung. The Master then proposed the usual loyal toasts, after which Sir James Paget proposed the toast of the evening, "The Memory of William Harvey."

He remarked that the reason why he had the honour of being asked to propose that toast was his relationship to his brother, who, he believed, made the proposal that there should be that tercentenary of the admission of William Harvey. He desired to remember that, and to speak as he thought his brother would have spoken if he had had the opportunity. He was sure that if he had been present he would have referred to the honour which was due to the college which Caius founded. He would have done that out of the deep sense of gratitude which he had for the College. For it was the Fellowship founded by Caius that led his brother to the study of medicine, and, on the occasion of that Fellowship which he held becoming vacant, to give himself entirely to it. To that he owed a great part of the happiness of his life, and he hoped he (the speaker) would not be deemed wrong if he said that indirectly he himself was also deeply indebted to Caius College, for it was through the large income which was associated with that Fellowship that his brother was enabled, out of his abundant generosity, to help him greatly in the study of his profession at St. Bartholomew's Hospital, of which Harvey was so great an ornament and honour. He wished that they knew more of the time and the work he did in Caius College. Indirectly Harvey owed to Caius himself the opportunity of being a student of the College. It was not, he thought, known whether Harvey was originally destined to be a student of medicine or physic, or whether he was led to it mainly by that which he found in that College, from the help and advantages given to the study of medicine and sciences. Harvey found there—and there alone, he thought, certainly amongst the Colleges of the University—a license for dissection. A license was obtained from the King to dissect in that College the bodies of criminals, and Dr. Venn, in the register of St. Mary's parish, had found records of two who were executed here in Harvey's time. The register said distinctly "They have been buried here after being anatomised in Caius College. He might add that the bodies were to be interred with great reverence, and the Masters and Fellows had to attend the funerals. From that College Harvey went to Padua, where he had the best learning from the best biological teachers of the time. He took the degree of doctor of medicine with the highest honour, and then he returned to the practice of his profession and the teaching of it in the University. Alluding to Harvey's discovery of the circulation of the blood, Sir James said he thought he might venture to say that that was the greatest discovery in biological science ever made by one man. He thought there never had been any one man to whom biology was so indebted as to Harvey for that discovery, and that was in the early part of his life. He supposed they could not now think of what would have been the progress of biology but for that discovery, neither could they form any just estimate of the honour due to Harvey for that discovery, which was to them now so plain, so evident, that one might wonder how it could ever have been doubted, but was then surrounded by difficulties which it seemed impossible ever to overcome. It was marvellous, if one looked back at it, to think what must have been the power of observation, the ingenuity, the constant, resolute industry of the man who could find that out, not only in the face of actual difficulties of inquiry, but in the face of those who were perfectly satisfied with their own opinions. He worked on and on until he brought out the best result he could obtain. He had shown by his discoveries, which had had even a greater influence on the progress of biological knowledge, the right method of inquiry. He had to find his results in the face of that full and perfectly-satisfied belief that all truth in such a science as that of medicine could be deduced from general principles then prevalent, and from the physiological doctrines which few men then dared to doubt. Nothing could have proved more than Harvey's results that the way to knowledge in biological science was through continual observation and experiment and recording. That was what Harvey showed, and it had never been forgotten. Again and again Harvey said in his works, and more especially in that admirable introduction to his work "De Generatione," that the way to knowledge was by observing, experimenting, and recording, and not by thinking. The same thought was expressed by John Hunter, who said, "Don't think; try." Those were words he (Sir James) would venture to say every one pursuing biology might well bear in mind. Both of those men were most earnest and profound thinkers. This could be traced in all their works, but that in which they distinguished themselves from other men of the same calling and the same pursuits was that they tried their thoughts. They tested them by every possible observation and experiment. They thought, and thought, and thought, but they were never satisfied with thinking; every thought they had was tried by experiment. When they remembered that Harvey was not only the greatest physiologist of the time, but the greatest physician, it was well to look and see as far as they could how much he himself followed that out, and he thought it would be found, unhappily, they had scarcely any record of Harvey's observations in practice. Repeatedly in his works that were published he stated that he intended to publish his medical observations. Now the whole of those, he supposed, were lost, and yet his (the speaker's) brother pointed out there was no certain knowledge at all either of the time or of the manner in which they were lost. Those observations would be of inestimable value if they could be found. They might hope that some of the younger Caius men would find out where those manuscripts were. It would be well if the MSS. could be published in *facsimile*, or in the same manner as the one done by the College a few years ago, when they at last found Harvey's lectures on anatomy and surgery. He asked them to drink to the memory of Harvey, who had made discoveries surpassing those ever made by any one man, and had showed the true and only sure methods by which biological science could be increased.

After the toast had been duly honoured the College "Carmen Caianum" was sung, the words of which were written by the President, Rev. B. H. Drury, and set to stirring music by Mr. C. Wood. An extra verse commemorative of Harvey and Glisson, also once a member of the College, was introduced into the song for this occasion.

Dr. Clifford Allbutt (Regius Professor of Physic) proposed the toast of "The Guests," and in doing so read a letter which had been received from the rector of Padua University, in which he expressed the pride of that University at having been the place where William Harvey had pursued his studies. Dr. Allbutt also referred to the sense of loss which was felt by all present at the death of Sir George Paget, who would, had he lived, have been the man of all others upon whom it would have been fitting that the duty of taking an important part in that celebration should have fallen.

Sir Andrew Clark responded, and said he desired in the name of his more distinguished fellow guests to give them his grateful thanks for permitting them to be present that evening.

Prof. Gairdner next proposed "The University," and said that the toast needed nothing on his part to recommend it. He could not conceive a greater eulogium upon the University of Cambridge than that it contained such magnificent representatives of ancient learning as their Vice-Chancellor, Dr. Peile; and at the same time eminent representatives of what he would venture to call the modern scientific method as the Professor of Medicine, Dr. Clifford Allbutt and of Physiology, Prof. Michael Foster. The University was an institution founded upon all that was best in human learning and in human experiments, and it will go on and prosper to the end of time. He proposed the health of the University and coupled with it the name of their distinguished Vice-Chancellor, Dr. Peile.

The Vice-Chancellor, in returning thanks, alluded to the great development of studies and of buildings in the University during the past thirty years. He was sorry to say that their rapid development had almost caused alarm in certain most important quarters. He read the other day one of the leading newspapers of England, which called attention to their unsatisfied spirit of innovation. He thought that that must have reference to some of their most recent developments of the engineering tripos. Yet surely it might have occurred to any one that the sciences of engineering were most closely connected with the study of mathematics, which was their chief glory in Cambridge. Possibly, also, it had reference to the development of agricultural science. Well, agricultural science was a very excellent thing. It seemed to him that, after all, some of the greatest discoveries in science had been made, not merely by students or by lecturers, but by men who had been carrying on professional work and working purely with mercantile aims. The duty of the University, he took it, was to encourage those studies as well as others. But there would always be a problem before them. At present the problem would raise the very, very old story—the limited means of the University. The problem was how far could they encourage new studies, which could never lead those who were following them to any great pecuniary rewards, although they might lead them to the rewards of learning. He thought that was a great problem. This year they had an examination in Oriental languages. There was one candidate for it; they had four examiners, and the cost of that examination, he supposed, was £50 or £60 to the University, which was perfectly right. It was just those studies which could not pay their way, which could never be supported without the help of endowments. He did not think the problem was so serious as it might seem at first. Two years ago, when his predecessor, Dr. Butler, resigned his office, he pointed out some of the needs of the University. Dr. Butler's clear and lucid statement brought forth one magnificent gift and nothing more. He (the speaker) in his turn, in the first year of his office, sent forth "a bitter cry" of the needs of the University. Yet that bitter cry brought forth nothing. Did it seem possible that after all a general cry might not be specially efficacious, while a request for special help might serve for a cry? He was happy to say that this seemed at last to solve the problem of how they could develop the newer studies with the help of those outside who were willing to support them. The engineering school had, by the labours of Prof. Ewing and Mr. Horace Darwin, received money, which he hoped would carry it on sufficiently. He believed so ancient an institution as the Observatory of Cambridge was going to ask for a new telescope to carry on its work. That being so, it seemed that partially at least the problem was solved. The problem concerning agricultural science had been solved by the liberal aid of the County Councils. Those bodies had come to their aid in the most generous manner, and given them enough to carry on their work for at least some years. He hoped, as he said before, they would see their way, not merely to maintain and develop those old institutions which had been from all times the glory of Cambridge, but also to carry on those newer studies and newer developments which would keep them in touch with the nation, and make them remembered for all times, and which, whatever developments might arise elsewhere, would make Cambridge one of our greatest centres of educational life.

In proposing the "Health of the Master and Fellows," the Right Hon. T. H. Huxley, who was enthusiastically received, said he was charged with a very pleasant duty, and one which could be happily performed without either gifts of eloquence or even those of voice, in which unhappily he was at present sadly deficient, and he would not be withdrawn from the simple discharge of that duty by the invitation which had been addressed to him by a previous speaker to enter upon the field of controversy. In proper time and place he imagined that he could hardly be said to have shown any unwillingness for the discussion of controverted questions, but in his judgment they were extremely inappropriate and out of place in a meeting of that kind, and he desired absolutely to abstain from that, and to confine himself to the business in hand, which was of a far more pleasant, and, he ventured to think, more profitable nature: it was to propose to them the health of the Master and Fellows of that College. All those who were present would understand the gratitude which they all felt for the generous and gracious hospitality which they had shown to them on that occasion, but it was a traditional hospitality, and it went back to the time when that important corporation, of which they were the present representatives, extended their hospitality to William Harvey, whose name and fame they were met to celebrate. He did not know whether the Master and Fellows of that time were aware of what they were doing in training and disciplining that young man—boy, indeed, to them—to make the best use of the faculties with which he was endowed, but he thought it lay to their credit that from that time to this, the hospitality which they extended to science—to biological science especially, and to that branch of it which was called the science of medicine very particularly—that that had been continued with unbroken openness and readiness. It was for that reason, he thought, that the large proportion of persons present in that room who were devoted to scientific studies would with the greatest possible cordiality drink the toast which he had to propose. For in this matter Gonville and Caius College occupied a position as isolated as it was honourable. He was aware that the studies of biological sciences, and more especially those which had relation to medicine, could not be cleared of the accusation then made against them of utility to mankind. He admitted to the full the charge that was made against those studies, but the present showed, and the future would show more strongly, that quite apart from the bearing of direct utility, it must be regarded as a happy instinct, if not as a purpose of intelligence, which had led that College for these 300 years to cherish and to promote those studies. It was on that ground they who were so deeply interested in its pursuits felt that they owed a debt of gratitude to the College, and he knew of no reason, except the fact that he once took an active part in those biological matters, which had led to his selection as proposer of the health of the College to them on that occasion. Sir James Paget had fully and exhaustively told them, in that admirable language which he had always at command, the great claims of Harvey upon their respect and veneration. He had justly told them that Harvey regarded himself, not merely as a discoverer, but as a propounder and champion of a new method. Dr. Venn was good enough to tell him before the dinner of a fact of which he (the speaker) was entirely ignorant: that before Harvey's time that College possessed what was called an "anatomer," a gentleman whose duties appeared to have been to dissect bodies, which were given over to him and others, to give the students of the College a practical contact with the nature of things. It was in that respect that modern science differed from ancient science; it was in that respect that Harvey was essentially modern. It was therefore to the wise provision of the founders of that College that they owed the beginning of that movement commenced in this country by Gilbert, followed up in Italy by Galileo, followed up conscientiously here by Harvey himself, which had led to the great modern development of scientific culture. They trusted that the hospitality which had hitherto been extended by that College to purely scientific investigations would be continued upon the lines laid down by Harvey. It might be that Harveys existed among them now, and the only thing they had to hope for, and to wish for was, that those Harveys of the future might not be compelled, as the Harvey of the past, to obtain a higher scientific training by going to the University at Padua. They hoped that in this University men would have the opportunity of obtaining the highest scientific culture which was to be given. That he understood was the object and purpose and desire of the Master and Fellows of that College, in inviting persons like himself to take part in that great celebration; he presumed they wished them to understand that they recognised Science as a fundamental branch of human culture, and that they would do what in them lay to promote that happy commemoration to which he ventured to allude.

The toast was drunk with enthusiasm.

The Master briefly returned thanks, and stated that it had given them very sincere pleasure to entertain so illustrious an assembly, and expressed his deep regret that Sir George Paget was not with them.

The Rev. B. H. Drury proposed the health of the younger members of the College, saying that they were the life-blood of their College to-day, the source of their vitality, without whom they would have really little cause for existence.

Mr. Keeble, Natural Science Scholar of the College, made a short and graceful reply.

At the conclusion of dinner a move was made to the Combination Room, where friendly and animated intercourse was kept up for some time, and it was late before the last of those engaged in the celebration separated for the night.

Breakfast was provided the following morning from eight to ten for those resident in College overnight, and by midday the guests had departed, leaving the courts once more to solitude, and to their hosts a keen feeling of satisfaction at the honour done to the memory of William Harvey and to the College by the recent presence of so representative and distinguished a gathering of visitors.

SOME POINTS IN THE PHYSICS OF GOLF.[1]

III.

IN Part II of this paper (NATURE, Sept. 24, 1891) the following statements were made:—

"The only way . . . of reconciling the results of calculation with the observed data is to assume that, for some reason, the effects of gravity are at least partially counteracted. This, in still air, can only be a rotation due to undercutting."

"And, as a practical deduction from these principles, it would appear that, to secure the longest possible carry, the ball should be struck so as to take on considerable spin———."

As these statements, and some of their consequences, have been strenuously denied, I must once more show at least the nature of the evidence for them.

It depends, in one of its most telling forms, upon the contrast between the length of time a well-driven ball remains in the air (as if in defiance of gravity) and the comparatively paltry distance traversed. Every one who thinks at all on the subject must see that, *without some species of support*, the ball could not pursue for six seconds and a half a course of a mere 180 yards, nowhere more than 100 feet above the ground.

In fact, if we assume the initial slope of the path to be 1 in 4, as determined for the average of fine drives by Mr. Hodge with his clinometer (NATURE, Aug. 28, 1890) the carry of a non-rotating ball will be approximately (in feet)

$$AgT^2,$$

where g is the acceleration due to gravity, T the time of flight in seconds, and A a numerical quantity depending on the resistance. The value of A varies continuously between the limits, 2 for no resistance, and 1 for infinitely great resistance. [It is assumed that the resistance is as the square of the speed.]

This formula gives, with the average observed value of T ($6^s{\cdot}5$, see Part II.) carries varying from about 900 down to 450 *yards!* The initial speed required varies from 416 foot-seconds upwards. The longest actually measured carry on record, when there was no wind, is only 250 yards. Unfortunately, in that case T was not observed, but analogy shows that it was probably much more than 7^s. Even if we take it as 7^s only, the "carry" ought to have been, by the formula (which is based on the absence of rotation), 522 yards at the very least!

I have purposely, in this example, kept to the case of an initial slope of 1 in 4; because those (and they are many, some of them excellent golfers) who altogether reject the notion that undercutting lengthens the carry, would of course in consistency refuse to believe that a long ball may sometimes start horizontally. But, to those who allow *this* statement, the fact that the action of gravity is occasionally largely interfered with, or even counteracted, is obvious without any numerical calculations. In fact, from my present point of view, initial slope is of little importance:—except, of course, in avoiding hazards. The want of it is easily made up for by a slightly increased rate of spin.

Another way of looking at the matter is to assume, from Mr. Hodge's data, 180 yards as a really fine carry, and thence to calculate by the formula the requisite time of flight. It varies from $4^s{\cdot}1$ to $2^s{\cdot}9$ according as the resistance, and therefore the necessary initial speed, are gradually increased; the former from *nil* to infinity, the latter from 132 foot-seconds upwards. Thus the observed time exceeds that which is really required when there is no spin, by 60 per cent. at the very least!

The necessity for underspin being thus demonstrated, we have next to consider how its effect is to be introduced in our equations. On this question I expressed a somewhat too despondent opinion in the previous part of this paper. A rather perilous mode of argument (which I have since been able to make much more conclusive) first suggested to me that the deflecting force, which is perpendicular at once to the line of flight and to the axis of rotation, must be at least approximately proportional to the speed and the angular velocity conjointly. But I tried (with some success) to verify this assumption by various experimental processes. These, as will be seen, led also to a numerical estimate of the magnitude of the deflecting force. [And I was greatly encouraged in this work by the opinion of Sir G. G. Stokes, who wrote:—"I think your suggestion of the law of resistance a reasonable one, and likely to be approximately true." This is quite as much as I could have hoped for.]

First: by the well-known phenomena called heeling, toeing, and slicing, which are due to the ball's rotation about a vertical axis. I have often seen a well-sliced ball, after steadily skewing to the right through a carry of 150 yards or even less, finally move at right angles to its initial direction, and retain very considerable spin when it reached the ground. Neglecting the effects of gravity, the equations of the path should be, in such a case,

$$\ddot{s} = -\frac{\dot{s}^2}{a},$$

$$\frac{\dot{s}^2}{\rho} = k\dot{s}\omega;$$

expressing the accelerations in the tangent, and along the radius of curvature, respectively. If we introduce the inclination, ϕ, of the tangent to a fixed line in the plane of the path, the second equation becomes

$$\dot{\phi} = k\omega,$$

showing that the time-rate of change of direction is proportional to the speed of rotation. The first equation gives, of course,

$$\dot{s} = V\epsilon^{-\frac{s}{a}},$$

where V is the initial speed.

The space-rate of change of direction, *i.e.* the curvature of the path, is thus

$$\frac{d\phi}{ds} = \frac{k\omega}{V}\epsilon^{\frac{s}{a}},$$

increasing in the same proportion as that in which the speed of translation diminishes; and, if we regard ω as practically unaltered during the short time of flight, the intrinsic equation of the path is

$$\phi = \frac{ka\omega}{V}(\epsilon^{\frac{s}{a}} - 1).$$

A rough tracing from this equation is easily seen to reproduce distinctly all the characteristics of the motion

[1] Part of the substance of a paper on the Path of a Rotating Spherical Projectile, read to the Royal Society of Edinburgh on June 5.

of a sliced, or heeled, ball. And, by introducing an acceleration in the plane of the path, constant in magnitude and direction, the path might be made to intersect itself repeatedly.

By the statement made above as to the whole change of direction in the course of a well-sliced ball, and with 5^s as the time of flight (for it, like the carry, is notably reduced by slicing) we have

$$\frac{\pi}{2} = 5k\omega.$$

Thus it is clear that we may easily produce rotation enough in a golf-ball to make the value of $k\omega$ as great as 0·3 or even 0·4. And this can, of course, be greatly increased when desired. This datum will be utilised later. The fact (noticed above) that the time of flight, and the carry, are both reduced by slicing, gives another illustration of the necessity for underspin when the time of flight is to be long, and the carry far.

Secondly: by a laboratory experiment which, I have only recently learned, is due in principle to Robins. (*An Account of Experiments relating to the Resistance of the Air.* R.S. 1747.) I suspended a wooden shell, turned very thin, by a fine iron wire rigidly fixed in it, the other end of the wire being similarly attached to the lower end of a vertical spindle which could be made to rotate at any desired rate by means of multiplying gear. Thin as was the wire, it was but slightly twisted in any of the experiments, so small was the moment of inertia of the wooden shell. The wire acted as a universal flexure joint; and, by lengthening or shortening it I could make the ball's mean speed, in small pendulum-oscillations, vary within considerably wide limits. I verified this result by substituting for the shell a leaden pellet of equal mass but of far smaller radius, as I feared that some part of the result might be due to stiffness of the wire, produced by torsion. But with the pellet the rotation of the orbit was exceedingly slow. Thus ω, and the average value of $\dot{s}$, could have any assigned values; and from the elliptic form and the rate of *rotation* of the orbit of the ball, the transverse force was found to be proportional to either of them while the other was kept constant. An exceedingly interesting class-illustration can be given by making the ball revolve as a *conical* pendulum, and while it is doing so giving it spin alternately with, and opposite to, the direction of revolution. The effects on the dimensions of the orbit and on the periodic time are beautifully shown. This form of experiment could be easily applied to considerable speeds, both of the translation and of rotation, if the use of a proper ball could be secured. But it cannot be made strictly comparable with the case of a golf-ball; as the speed of translation can never much exceed that for which the resistance is as its first power only. [Robins' suspension was bifilar, and the rotation he gave depended more on the twisting of the two strings together than on the torsion of either. In this mode of arrangement it is difficult to measure the rate of spinning of the bob, and almost impossible to vary it at pleasure.]

We must next say a few words as to the manner in which the spin, thus *proved* to have so much influence on the length of the carry, is usually given. I pointed out, in the earliest article I wrote on the subject, "The Unwritten Chapter on Golf" (*Scotsman*, Aug. 31, or NATURE, Sept. 22, 1887), that spin is necessarily produced when *the direction of motion of the club-head*, as it strikes the ball, *is not precisely perpendicular to the face.* Now, even when the head is not purposely laid a little back in addressing the ball, (many of the longest drivers do this without asking Why) it must always become so in the act of striking if the player stand ever so little behind the ball:—especially if, as Mr. Hutchinson so strongly urges upon him, he makes the path of the head at striking as nearly straight as possible. Mr. Hutchinson gives a highly specious, but altogether fanciful, reason for this advice. We now see why the suggestion is a really valuable one. A "grassed" club, and especially a spoon, gives this result more directly. As soon as I recognised this, I saw that it furnished an explanation of a fact which had long puzzled me:—viz. that one of my friends used invariably to call for his *short* spoon when he had to carry a bunker, so distant that it appeared impossible of negotiation by anything but a play-club. And, if the ball be hit ever so little under the level of its centre, with the upper edge of the face, very rapid underspin may be produced. This was probably at least one of the objects aimed at (however unwittingly) by the best club makers of last generation, for they made the faces of drivers exceptionally narrow. Some time ago I proposed, with the same object in view, to bevel the face by deeply rasping off both its upper and lower edges:—thus in addition saving the necessity for the "bone."

I have neither leisure nor inclination to attempt (for the present at least) more than a first approximation to the form of the path under the conditions just pointed out. Anything further would involve a laborious process of quadratures, mechanical or numerical, only to be justified by the command of really accurate data as to the values of a and V. I shall therefore at once assume that neither gravity nor the spin affects the translatory speed of the ball. (If the spin have such an effect, it will be taken account of sufficiently by a slight change in the constant of resistance; and the effect of gravity on a low trajectory is mainly to produce curvature which, in this case, is to a great extent counteracted by the spin. It is easy to see that the effects of this ignoration of gravity, in the tangential equation of motion, are to make the path rise a little too slowly at first, then too fast; to make it rise too high, and descend at too small a slope.) Hence we may keep the first equation of motion above, and write the second as

$$\dot{\phi} = k - \frac{g}{\dot{s}}$$

where ϕ is reckoned positive in the ascending part of the path; and k is written for $k\omega$, its dimensions being those of angular velocity. With the help of the value of $\dot{s}$, above, this becomes

$$\frac{d\phi}{ds} = \frac{k}{\mathrm{V}}\epsilon^{\frac{s}{a}} - \frac{g}{\mathrm{V}^2}\epsilon^{\frac{2s}{a}}.$$

In x, y coördinates, x horizontal, this is nearly

$$\frac{d^2y}{dx^2} = \frac{k}{\mathrm{V}}\epsilon^{\frac{x}{a}} - \frac{g}{\mathrm{V}^2}\epsilon^{\frac{2x}{a}}.$$

Thus the x coördinate of the point of contrary flexure is found from

$$\epsilon^{\frac{x}{a}} = \frac{k\mathrm{V}}{g},$$

so that there must be such a point, *i.e.* the path is concave upwards at starting, if kV be ever so little greater than g.

Again

$$\frac{dy}{dx} = e + \frac{ka}{\mathrm{V}}(\epsilon^{\frac{x}{a}} - 1) - \frac{ga}{2\mathrm{V}^2}(\epsilon^{\frac{2x}{a}} - 1)$$

where e is the initial slope. The x coördinate of the vertex is found by putting

$$\frac{dy}{dx} = 0.$$

Finally, the approximate equation of the path is

$$y = ex + \frac{ka^2}{\mathrm{V}}\left(\epsilon^{\frac{x}{a}} - 1 - \frac{x}{a}\right) - \frac{ga^2}{4\mathrm{V}^2}\left(\epsilon^{\frac{2x}{a}} - 1 - \frac{2x}{a}\right).$$

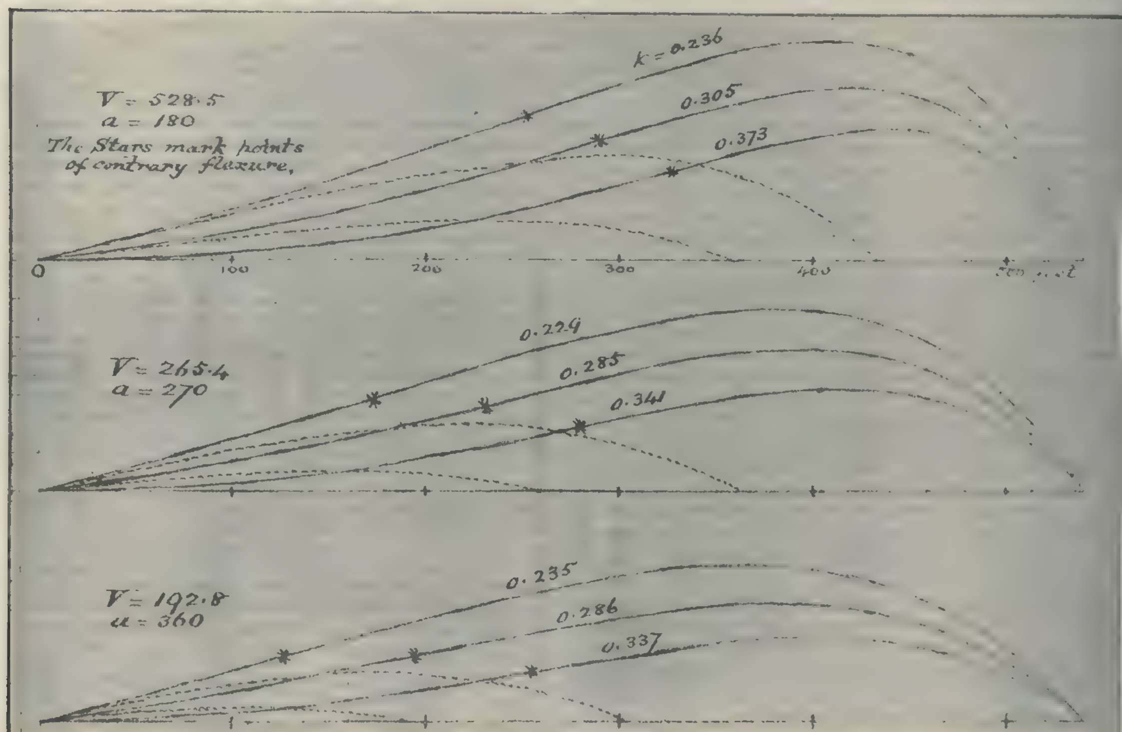
To deal expeditiously with these equations I formed a table of values of the various factors in brackets, by the help of Glaisher's data of natural antilogarithms (*Camb. Phil. Trans.* xiii, 243). Next, I utilized in the equation

$$\mathrm{V}t = a(\epsilon^{\frac{x}{a}} - 1)$$

the well ascertained data $6^s.5$ for the time of flight, and 540 feet for the carry, thus obtaining a general expression for V in terms of a. Then, in consequence of the want of accurate data, I chose three values of a, one considerably less than, the second nearly equal to, and the third considerably greater than, that which results from Bashforth's experiments with iron spheres. Thus I found the following values:—

a	V
180	528
270	265·4
360	193.

fault. I regret this for the additional reason that I should have liked to add an illustration of an extremely exaggerated path in which e is (say) zero, and k unity at the least. Under conditions of this kind there might be kinks in the path! For a similar reason I cannot attempt to work out the effect of wind with any attempt at precision, at least in the case when the drive is against the wind and the upward concavity of the path becomes in consequence much more prominent. It is easy in every case to *form* the more exact equations, but the labour of treating them even to a rough approximation would be considerable.



Next, with each pair of these numbers, and with the successive values $\frac{1}{4}$, $\frac{1}{8}$, and o for e, I found k from the condition that $y = 0$ for $x = 540$. These values of k are of course greater as e is less, and also as a is less. But all are found to lie between the limits derived, above, from the data for a sliced ball. All the constants being thus found, the curves were easily traced by a few points:—and the position of the maximum ordinate was found as above. For contrast, I have put in (dotted) the paths of drives corresponding in all respects with the others, except the absence of rotation. Poorly as these show, they are probably unduly favoured at the expense of the others, as I have taken a the same for each of the group; though it is probably reduced by the spin, so that rotation increases the direct resistance. The comparison of these with those in which rotation has a share shows that, though strength and agility are undoubtedly of importance in long-driving, even a store of these qualities equalling in amount that of a full-sized tiger is comparatively inefficient as against the skill which imparts a sound undercut. For here, as elsewhere, the race is not to the swift, nor the battle to the strong. Craft beats Kraft all the world over! La Puissance! ce n'est pas frapper fort, mais frapper juste!

From the very nature of the process I used in approximating, none of these curves can be quite trustworthy, those giving the greater elevations being most at

I am engaged at present in endeavours to find something like a proper value of a, or of V, above; so as to have reasonable confidence in my data before I engage in what promises to be a heavy task. Of course, if I can obtain a satisfactory value of one of them, that of the other would follow. But independent determinations of both would enable me to subject the theory to the most complete test imaginable. I am inclined to think that the value of a (280 feet), which I calculated from Bashforth's data, is too large (*i.e.* it makes the resistance too small) for a golf-ball:—and thus that the true path is intermediate in form between those of the first and of the second series in the cut. For the initial speeds required, even with $a = 270$, to give a carry of 540 feet *without spin*, are 462 and 653 foot-seconds for slopes of 1 in 4 and 1 in 8 respectively:—the corresponding times of flight being only $3^s.7$ and $2^s.6$.

P. G. TAIT.

NOTES.

WE are glad to record that the Council of the Imperial University of Kasan has elected Prof. J. J. Sylvester honorary member of the University.

THE Albert Medal of the Society of Arts for the present year has been awarded to Sir John Bennet Lawes and a like medal to Mr. John Henry Gilbert "for their joint services to scientific agriculture, and notably for the researches which throughout a period of fifty years have been carried on by them at the experimental farm, Rothamsted."

PROF. W. H. PICKERING, the Director of the Harvard College Mountain Observatory at Arequipa, is expected to be in London in the course of a few days.

THE distribution of prizes to the students of Charing Cross Hospital Medical School will take place at the School on July 4, at three o'clock precisely. The Right Hon. the Baron de Worms, M.P., F.R.S., will occupy the chair.

THE Dental Hospital of London will hold a *conversazione* at the Royal Institute Galleries, Piccadilly, on July 14. There will be a distribution of prizes at 8.30 p.m. by Prof. Sir W. H. Flower, K.C.B., F.R.S.

ACCORDING to Dalziel's agency, a cyclone passed over Williamstown and its immediate vicinity on June 21. Its path was six miles long by half a mile wide, and in this track not a house, barn, or tree was left standing. The wind-rush was followed by a terrific downpour of rain. About twenty persons lost their lives.

DR. NANSEN and the members of his expedition to the North Pole sailed from Christiania on Saturday, and arrived at Laurvig on the following day. After taking on board two covered boats, to be used in case the members of the expedition are compelled to leave the *Fram* in the ice, the vessel proceeded on her voyage. Reuter says that intelligence has been received from Siberia that twenty-six dogs, for service with the expedition, have been brought down to the mouth of the River Olensk. Parties have been sent out to leave stores of provisions for twelve men at two places on the islands of Kotelnoi and Liakow. These depots will be inspected in 1894 and 1895. Sealers report that the sea around these islands was quite open in 1888, 1889, and 1890, while in 1891 and 1892 there was little ice in the vicinity.

INFORMATION with regard to the social, physical, and mental condition of children is being accumulated by the committee appointed by the International Congress of Hygiene and Demography. Nearly 30,000 children, chiefly in London Board Schools, have been inspected, and important facts have been obtained as to the variation of educational requirements of boys and girls, and the causes of low mental development. It is desired to extend the inquiry among 100,000 children before submitting the statistics to a complete investigation. For this purpose Sir Douglas Galton, writing from the Parkes Museum, has made an appeal for financial help. The deep importance of the work is fully understood by educationalists, hence there should be no difficulty in obtaining sufficient funds to render the investigation as comprehensive as possible.

A SPECIAL general meeting of the Royal Geographical Society will be held on July 3 in the hall of the University of London, Burlington Gardens, to consider the proposal that ladies should be admitted as ordinary Fellows. On the evening of the same day the Earl of Dunmore will give a paper on his "Journeys in the Pamirs and Central Asia."

DR. M. MŒBIUS, of Heidelberg, has been appointed Director of the Botanic Gardens at Frankfort-a-M., and Dr. F. Pax, Director of the Botanic Garden at Breslau.

THE French Academy has awarded the Prix Desmazières to M. P. Viala, for his researches on viticulture; the Prix Montagne to M. l'Abbé Hue, for his work in lichenology; and the Prix de la Fons Mélicocq to M. Maseleff, for his work on the Botanical Geography of the north of France.

SOME interesting scientific documents changed hands at the sale this week of the library of the late Lord Brabourne. Among the lots was a quantity of the correspondence of Sir Joseph Banks, to whom Sir Edward Knatchbull, Lord Brabourne's father, was executor. An interesting autograph letter from John Hunter, dated 1792, appears to be one covering the despatch to the Royal Society of his paper on the natural history of the common bee. He hopes Sir Joseph and his worthy council will think the results of twenty years of observation and experiment suitable for publication in the transactions, and details some of the obstacles which had prevented an earlier forwarding of the paper. About 1830 the Royal Society claimed and received from Sir Edward Knatchbull the letters and papers of Sir Joseph Banks, referring to the society over which he so long presided, but evidently this particular letter was overlooked. A document, apparently in the handwriting of Duhamel du Monceau, is an appeal to Sir Joseph on behalf of Dolomieu, the French mineralogist, imprisoned at Messina, by order of the Neapolitan Court, as he was returning to Europe from serving on the scientific staff which accompanied Bonaparte's expedition to Egypt. It is signed by thirty-nine famous men of science of the time, including Cuvier, Lamarck, Laplace and Lalande.

THE weather during the past week has been of a decidedly unsettled type. On Thursday, the 22nd inst., a depression advanced over Scotland and moved slowly to the North Sea and Norway, causing some rain over most parts of these islands; in the north-east of Scotland the fall amounted to 2·2 inches in forty-eight hours, and a moderate gale blew from the north-west on our northern coasts. During the early part of the present week important depressions advanced over the western parts of the country from off the Atlantic, causing exceptionally heavy rain in the south of Ireland, the fall at Roche's Point on Tuesday morning registering 1·1 inch, while the amount was very considerable in many other parts of the kingdom. During the first part of the period the temperature was from 25° to 30° lower than in the previous week; the maxima rarely reached 70° in any part of the country, while in the north the highest daily readings were frequently below 60°, but on Tuesday the temperature rose considerably in most parts, and reached 80° at Cambridge. The *Weekly Weather Report* of the 24th inst. showed that the rainfall exceeded the mean in the east of Scotland only. Bright sunshine was above the average in Ireland and the greater part of England; the percentage of possible duration amounted to 77 in the Channel Islands.

MR. W. H. PREECE, F.R.S., in giving evidence before the joint committee of Lords and Commons on Electric Powers Protective Clauses, is reported to have shown a series of diagrams illustrating the effect upon the earth of the City and South London Electric Railway. That railway did not designedly use the earth, but the return circuit was made by means of the rails, and also by the tubes or tunnels. Currents were produced which had disturbed the observing instruments at Greenwich, and which had been traced as far as North Walsham, in Norfolk. Last year the disturbances began to increase, and his attention was called to the fact that in Clapham Road there was a chemist who had in his shop window an instrument for recording the passing movement of every train on the electric railway, the instrument being connected on one side with gas-pipes, and on the other with water-pipes in the house. He had caused the currents to be measured, and they were found to be sufficient to light a lamp or, as he had proved, to ring one of the division bells of the House of Commons. Another difficulty had occurred in connection with the railway block system. Some years ago the London and North-Western Railway lighted Holyhead Harbour by electricity. The effect of the five arc-lamps employed was to break down the block signals in the district within a mile. But the difficulty was removed by supplying metallic circuits to the signals. At Blackpool the disturbing currents from the electric tramway had lowered a block-signal on the railway and fired a time gun at the same moment, a minute or so before the time when the gun ought to have been discharged.

In the recently published number of the Proceedings of the Société Française de Physique there is an account of a standard condenser formed by two plates of silvered glass separated by three blocks of quartz accurately worked to the same thickness. The instrument almost exactly realises a theoretical condenser, as the central part is only separated from the guard-ring by a narrow line along which the silver has been removed. The only disadvantage is that the insulation is rather bad, and when the air is not perfectly dry there is a small current between the central disc and the guard-ring. To get over this difficulty the author (M. P. Curie) joins the electrometer to the continuous plate of the condenser, charges the central disc of the other plate with the battery, and connects the guard-ring with the earth. Under these conditions the field of force between the plates is no longer uniform, but the charge of the condenser is the same as in the ordinary arrangement. With this arrangement the insulation is all that can be desired, as the quartz blocks are very good insulators, and little affected by moisture in the air.

A similar condenser to that described above has been employed by M. Abraham in his determination of the ratio between the electromagnetic and electrostatic units (see Proceedings of Société de Physique, p. 332, 1893). The method employed for measuring the distance between the plates is as follows. In front of the space between the plates a finely-divided glass scale is placed with its plane perpendicular, and the lines of the graduations parallel to the plates. The silvered plates constitute excellent mirrors, and give a series of images of the divisions of the scale, the distances between which were measured by means of a microscope. This method gives the mean distance between the plates, which was found to vary each time the instrument was set up, and to differ slightly from the length of the quartz blocks employed to separate the plates.

The photographic study of sources of light by means of a carefully graduated series of exposures was first applied with great success by M. Janssen to the investigation of the minute structure of the solar surface. M. Crova has applied a similar method to the study of the carcel standard and the electric arc. A contrast between the various parts of the magnified photographic image of the carcel flame does not appear until the exposure is reduced to the minimum necessary to secure an impression, and to bring out this contrast the negative must be developed slowly and subsequently intensified. Four photographs thus obtained were exhibited at a recent meeting of the French Academy. The axis of the flame appears dark, and the zone of combustion exhibits two bright lines representing the external and internal surfaces of combustion of the hydrocarbons, with a dark line between them corresponding to the space where combustion is incomplete. Photographs of the flames of a candle, an amyl-acetate burner, and a bat's-wing gas jet were also exhibited, showing analogous phenomena. The same method applied to the arc light yielded some interesting results. As the time of exposure was reduced the arc gradually vanished, the negative carbon was reduced to a very small surface, and the positive carbon exhibited a surface riddled with dark spots, and granulated like the surface of the sun in M. Janssen's photographs. These granulations could be seen in violent motion on the ground glass screen of a camera with the lens sufficiently stopped down. It follows that it is not admissible to screen off all but a very small portion of the luminous source in order to reduce the amount of light in the same proportion as the area of luminous surface. With very small surface elements both the amount of light and the temperature, and hence also the tint of the light, may be constantly changing.

Herr von Lupin, of Munich, has recently called attention to two thermometer liquids as free from certain drawbacks of the spirit thermometer. One of these is sulphuric acid diluted with water. According to experiments by Sohncke, the quantity of water removed by distillation in the thermometer-tube was a minimum even when the free end was surrounded with ice; and (what is still more important) in a short time this very small quantity was reabsorbed. The expansion of the liquid is approximately constant. In a recent expedition by Herr Vogel to Central Brazil these minimum thermometers were used, and found to act very well. The other liquid referred to is chloride of calcium in spirit (10 to 15 per cent. of the anhydrous salt is best). This is specially recommended for medical use, because its pronounced colour enables it to be more easily read at night than the mercury thermometer. Here, too, there is no distillation-error. A further advantage is that the thermometer takes the body-temperature very quickly (in about three minutes). The regularity of expansion between 0° and 50° C. is good, though not in the same degree as with sulphuric acid; and the proportion of calcium chloride is here influential. The solution, like that of sulphuric acid, does not solidify even in the artificial cold of evaporating carbonic acid snow; and with the proportion of salt given, no salt is separated out in the bulb.

To the current number of the *Zeitschrift für physikalische Chemie* Herr Altschul communicates from Prof. Ostwald's laboratory a series of observations on the critical constants of some fatty and aromatic hydrocarbons. Unlike most observers in this field the author thus deals with chemically related substances which have a comparatively simple structure. With the ascent of a homologous series it appears that the critical temperatures increase and the critical pressures decrease at rates which gradually diminish. Chemical constitution also affects the magnitudes of the critical values, the three metameric xylenes, for example, have different constants. From his observations the author deduces the values of (a) and (b) in Van de Waals's equation, Guye's critical coefficient, &c., and traces relationships between their magnitudes.

Is colour-blindness a product of civilisation? An investigation described in *Science* by Messrs. Blake and Franklin, Physical Laboratory, Kansas University, favours an affirmative answer to the question. Of 159,732 persons tested in Europe and America, nearly four per cent. were found to be colour-blind. But when the ordinary Berlin worsteds were used to test the colour perception of a number of Indians, representing many tribes, only 3 in 418, or 0·7 per cent., were found to be deficient. These were full-blooded Indians, and all males. It appears, therefore, that, as with civilised peoples, the percentage of colour-blind males is greater than that of females.

The peculiar phenomenon sometimes observed near the Wetter Lake in Sweden, and called by the natives *Motalaströms stadnande*, the standing still of the Motala river, has been the subject of speculation ever since the times when it used to be regarded as a miracle and a portent. The Motala river emerges from the Wetter Lake, and the phenomenon in question consists in the cessation of the flow and the drying up of the bed, accompanied by a retention of water within the lake.

According to Block, this is due to a sudden sharp frost, which freezes the river to the bottom at a shallow place without allowing time for the formation of mere surface ice. It is probable that a strong east wind is a necessary condition, and that the detention of the water is aided by the reeds growing near the outflow of the lake. A collection of records of the occurrence has been made by Herr Robert Sieger in a paper on the oscillations of lake and ocean levels in Scandinavia, which appears in the *Zeitschrift der Gesellschaft für Erdkunde*. He finds six observations during the sixteenth, twelve during the seventeenth, and eighteen in the eighteenth century. He does not, however, think that the general level of the lake is perceptibly influenced by the phenomenon.

Two organisms resembling the cholera bacillus have recently been obtained by Bujwid from water during an outbreak of cholera ("Ueber zwei neue Arten von Spirillen im Wasser," *Centralblatt für Bakteriologie*, vol. xiii. 1893, p. 120). These are designated as *Bacillus choleroides* α and β in consequence of their striking resemblance to Koch's cholera organism. It is quite possible, however, that these forms may really be identical with the original cholera spirillum, and that the differences noted in cultures and microscopic specimens may be simply due to the modifications undergone by the latter after long residence in artificial culture media. Finkelnburg ("Zur Frage der Variabilität der Cholera bacillen," *ibid.* p. 113) has made careful comparative studies of cholera bacilli obtained from different centres during the recent cholera epidemic. He found that whereas those obtained from Paris and Hamburg respectively were practically identical, they presented slight but distinct deviations from the laboratory specimen of Koch's spirillum originally brought from India. Finkelnburg points out as the result of his investigations that in the course of the many years during which this organism has been cultivated outside the human body and in foreign surroundings, it has apparently undergone a gradual attenuation, and that in this process of degeneration it has lost some of its vital energy. Whether it has also suffered a diminution in its toxic properties Finkelnburg has not yet determined, but concludes by emphasising the importance of such an inquiry as calculated to throw some light on the possible future attenuation of the virus during its residence in Europe.

Mr. F. C. Selous, who has spent twenty years in South Central Africa, has now completed the book in which he describes his experiences in the country. Messrs. Rowland Ward and Co. will publish the work in the autumn.

A book by Capt. Hayes on "The Points of the Horse," and dealing chiefly with equine conformation, will be published next month by Messrs. Thacker and Co.

The trustees of the South African Museum have issued their report for the year 1892. Mr. Roland Trimen, F.R.S., the curator of the museum, reports favourably of the condition of the collection generally. The donations amount to 4857 specimens, presented by 90 donors, as against 4677 specimens presented by 105 donors in the year 1891. For a long time extended accommodation has been needed, and we are glad to note that the Parliament granted the application for a sum of £20,000 to satisfy the want. Designs for the new museum building have been invited, and the work will be proceeded with as soon as possible.

The proceedings of the Bath Natural History and Antiquarian Field Club, No. 4, contains an article by the Rev. H. H. Winwood, on some deep-well borings made in Somerset and one or two other counties. A description is given of the thickness and nature of the beds pierced in each case.

The second part of "Phycological Memoirs," being researches made in the botanical department of the British Museum, contains, among other papers, several notes on the morphology of the Fucaceæ. Mr. George Murray contributes a comparison of the marine floras of the warm Atlantic, Indian Ocean, and the Cape of Good Hope.

A series of monographs dealing with the principal gold fields of Victoria are being prepared under the direction of Mr. A. W. Howitt, the Secretary for Mines. A report by Mr. E. J. Dunn, on the Bendigo gold-fields, forms one of the number. According to Mr. Dunn, the primary features of this gold-field are that the mass of silurian strata which he investigated is made up of bands auriferous to varying degrees or barren of gold, and that the whole of the strata are bent along certain lines into anticlinal folds with intervening synclinals. The report is illustrated by numerous plans, sections, and diagrams.

The Scientific Society of the University College of Wales has issued its first report. Natural history specimens collected during the excursions have been identified, and the results recorded in the report furnish some useful information with regard to Welsh fauna and flora.

At the meeting of the Russian Chemical Society on March 16 K. D. Khroushchoff, who is well known for his remarkable synthesis of hornblende and other minerals, made a communication to the effect that he also has obtained artificial diamonds in a way similar to that of Moissan. He prepared a carbonide of silver, Ag_2C, obtained by the heating of cuminate of silver. At the temperature of boiling, silver absorbs about six per cent. of carbon, which is given out on cooling. Cooling was effected rapidly, as by Moissan, so that a crust was formed which prevented the increase of volume of the metal, and produced a considerable interior pressure. It appeared that part of the dissociated carbon had the properties of diamond—the dust consisting of minute broken crystals and laminæ, colourless and transparent, strongly refracting light, quite isotropic, and scratching corundum; on combustion they give carbon dioxide, with an insignificant amount of ash. Diamond dust obtained in this way was shown to Prof. Beketoff the day after Moissan's communication had been received at St. Petersburg.

Further interesting experiments with the electric furnace are described by M. Moissan in the current number of the *Comptes Rendus*. By attaching to the furnace a condensing tube of copper shaped like the letter U, and so constructed as to be surrounded by an outer jacket of cold water constantly changing under high pressure, M. Moissan has been enabled to distil and condense most of the elements which have hitherto been found so refractory. When a piece of metallic copper weighing over a hundred grams was placed in the inner crucible of the furnace and subjected to the arc furnished by a current of 350 ampères, brilliant flames shot forth from the apertures through which the carbon terminals were inserted. The flames were accompanied by copious yellow fumes, due to the combustion of the issuing vapour of copper in contact with the oxygen of the air. After the expiration of five minutes nearly thirty grams of copper had been volatilised. Under the cover of the furnace an annular deposit of globules of metallic copper was found, and upon examination of the condensing tube a large proportion of the volatilised copper was discovered condensed in almost a pure state. It has long been known that silver is volatile; it is now found that at the temperature of an arc of the above description silver may be brought to full ebullition in a few moments, and it distils with ease, condensing in the copper condenser in the form of small globules, whose size varies from that of small shot to spherules of microscopic dimensions, and a certain proportion is usually deposited in the form of arborescent fragments. Platinum fuses in a few minutes, and very soon after commences to volatilise, and condenses in the U-tube in brilliant little spheres and fine dust. Aluminium distils very readily, and condenses in the form of a grey powder, containing admixed spherules exhibiting brilliant metallic lustre. Tin likewise distils with facility, and the condensed product usually contains a considerable proportion of a curious fibrous variety of the metal. The distillation of gold in the electric furnace is particularly interesting. Abundant fumes of a light yellowish green colour are emitted at the electrode apertures, and the metal is deposited in the condenser in the form of a powder, exhibiting a beautiful purple sheen. The powder consists of minute regular spheres which, when examined under the microscope, appear to reflect the usual yellow colour of gold. Upon the under side of the cover of the furnace three distinct annular deposits are observed, the inner one consisting of yellow globules of considerable size, round which is a metallic deposit of smaller spheres of such a size as to reflect a bright red tint, and outside this is an annular sublimate of a deep purple colour. Manganese is remarkably volatile; a quantity of the metal weighing four hundred grams entirely volatilised in ten minutes. Iron is likewise readily distilled, and is deposited in the form of a grey powder, among which are interspersed numerous small particles exhibiting brilliant surfaces.

NOT only are the metals capable of distillation at the temperature of the electric arc. Silicon rapidly volatilises and condenses in the copper condensing tube in minute spheres and dust. Carbon becomes almost immediately converted to graphite, which distils over into the condenser and deposits in the form of light semi-transparent plates, which by transmitted light exhibit a beautiful chestnut colour. Distilled carbon would thus appear to consist of the fourth variety of the element recently described by M. Berthelot. The refractory alkaline earths appear also to be capable of distillation in the electric furnace. The experiment succeeds best, however, with a more powerful arc. Employing an arc furnished by a current of a thousand ampères, M. Moissan has distilled one hundred grams of lime in five minutes, the vapour condensing in the copper tube like fine flour. Magnesia passes over somewhat more slowly than lime, but its distillation is one of the prettiest of these remarkable experiments, the tints assumed by the escaping fumes and the brilliance of the incandescent vapour being particularly striking.

NOTES from the Marine Biological Station, Plymouth.—The following list completes the summary begun last week of the records given during the last six months of the breeding seasons of marine animals at Plymouth. Among Mollusca, the Prosobranchs *Littorina littoralis*, *Nassa reticulata*, *Buccinum* (*undatum*), *Purpura* (*lapillus*), *Murex erinaceus* and *Capulus hungaricus*, the Opisthobranchs *Lamellaria perspicua*, *Aplysia punctata*, *Philine aperta*, many Nudibranchs, and the Cephalopod *Loligo media*; among Crustacea, the Cladocera *Podon* and *Evadne*, various Cirripedia, the Leptostracan *Nebalia bipes*, several Amphipoda, the Schizopoda *Siriella jaltensis*, *Leptomysis mediterranea*, *Macromysis flexuosa* and *inermis*, *Schistomysis arenosa*, the Cumacean *Pseudocuma cercaria*, the Macrura *Crangon* (*vulgaris*), *fasciatus* and *sculptus*, *Palæmon* (*serratus*), *Palæmonetes varians*, *Pandalus annulicornis* and *brevirostris*, *Hippolyte Cranchii*, *Virbius varians*, *Pagurus lævis* and *Bernhardus*, *Galathea squamifera*, the Brachyura *Porcellana longicornis* and *platycheles*, *Carcinus* (*mænas*), *Portunus depurator*, *holsatus*, *arcuatus*, *marmoreus* and *pusillus*, *Cancer* (*pagurus*), *Pilumnus hirtellus*, *Xantho floridus* and *rivulosus*, *Eurynome* (*aspera*), *Stenorhynchus phalangium* and *tenuirostris*; among Echinodermata, *Echinus miliaris*, *Asterina gibbosa*, and *Amphiura elegans*; among Tunicata, *Botryllus violaceus* and *Styclopsis grossularia*; and among Cephalochordata, *Amphioxus lanceolatus*, have been recorded. It should also be mentioned that the following larvæ have been townetted in large numbers at certain periods:—Veligers, *Cyphonautes*, *Nauplii* and *Zoeæ*, and the various larvæ of Echinoderms.

THE additions to the Zoological Society's Gardens during the past week include two Mozambique Monkeys (*Cercopithecus pygerythrus*, ♂ ♂) from East Africa, presented respectively by Mr. J. B. Tomkins and Mr. B. J. Travers; two Llamas (*Lama peruana*, ♂ ♀) from Peru, presented by Lady Meux, F.Z.S.; a Rose-crested Cockatoo (*Cacatua moluccensis*) from Moluccas, presented by Mrs. Bason; a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, presented by Mr. Lewis Baily; a Cinereous Waxbill (*Estrelda cærulescens*), two Hooded Finches (*Spermestes cucullata*), a Grenadier Weaver Bird (*Euplectes oryx*) from West Africa, an Amaduvade Finch (*Estrelda amandava*), two Nutmeg Finches (*Munia punctularia*), a Black-headed Finch (*Munia malacca*) from India, presented by Mr. W. L. Jeffrey; two Greater Spotted Woodpeckers (*Dendrocapus major*) British, presented by Miss Miriam A. Birch Reynardson; two Alexandrine Parrakeets (*Palæornis alexandri*) from India, presented by Mr. Wyndham Gibbs; two Brazilian Tortoises (*Testudo tabulata*) from Trinidad, W.I., presented by Mr. J. S. Toppin; an Ocellated Skink (*Seps ocellatus*) from Malta, presented by Col. C. H. Rooke; two Infernal Snakes (*Boodon infernalis* jv.) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; two Emus (*Dromæus novæ-hollandiæ*) from Australia, deposited; two Collared Fruit Bats (*Cynonycteris collaris*), a Burrhel Wild Sheep (*Ovis burrhel*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMET FINLAY (1886 VII.).—The ephemeris for this comet for this week is as follows:—

12h. *Paris. M.T.*

1893.		R.A. (app.) h. m. s.		Decl. (app.) ° ′
June 29	...	2 52 20	...	+14 8·7
30	...	2 57 5	...	14 31·9
July 1	...	3 1 49	...	14 54·6
2	...	6 33	...	15 16·9
3	...	11 16	...	15 38·6
4	...	16 0	...	15 59·9
5	...	20 42	...	16 20·6
6	...	3 25 24	...	+16 40·9

STARS HAVING PECULIAR SPECTRA.—On an examination of the stellar spectra photographs taken at Cambridge (U.S.A.) and Arequipa it has been found (*Astronomy and Astrophysics* for June) that several of them have spectra which qualify their designation as "interesting objects."

The following list we take from the note referred to:—

Designation	R.A. 1890. h. m.	Decl. 1890. ° ′	Mag.	Description.
B.D. +49°·41	0 12·2	+49 44	9·4	Type IV.
B.D. −13·893	4 24·5	−13 17	5·8	F line bright.
A.G.C. 5429	4 43·8	−36 23	7½	Type IV.
A.G.C. 11890	8 42·4	−29 21	7½	Type IV.
—	15 27·0	−71 32	—	Type III. (H lines bright).
A.G.C. 22838	16 47·9	−44 50	8·2	Type V. (bright lines).
Z.C. XVIII.h 56	18 3·3	−63 38	9½	Type III. (H lines bright).
A.G.C. 26129	18 59·7	−38 17	8½	Type IV.
B.D. −21°·6376	23 6·3	−21 32	9·0	Type IV.

All these stars, it will be noticed, with the exception of the first two, have a large southerly declination.

Photographic charts of the region about Z.C. XVIII.h 56 have confirmed the variability of this star. Among other results, photographs of U Virginis, V Boötis, S Geminorum, T Cassiopeiæ, R Piscis Australis et Geminorum, show that these stars give bright hydrogen lines.

THE SUN'S MOTION THROUGH SPACE.—The methods that have generally been adopted for determining the direction of the sun's motion have been based on the same general principle and the position of the apex of the direction of motion has been deduced by analysing the proper motions of the stars. A new determination on different lines (a spectroscopic method) appears in the *Astronomical Journal* (No. 298), and in this Mr. A. D. Risteen, the writer, bases his method on the three assumptions (1) that the stars used in the computation have no tendency to drift in any particular direction; (2) that their absolute velocities do not depend upon their apparent positions in the heavens; (3) that their absolute velocities are not functions of their own directions. Another minor assumption is that the absolute velocity of a star is not a function of the star's brightness. The values he gets for the right ascension and declination are given in the following table, in which we include those of Bischoff, Ubaghs, L. Struve, and Stumpe.

	R.A.	Decl.
Bischoff	285·2	+48·5
Ubaghs	262·4	26·6
L. Struve	273·3	27·3
Stumpe	285·1	36·2
Risteen	218·0	45·0

The value Risteen obtains shows that the method may prove a very valuable one in future when more stars can be included (here about 42 observation-equations are used), and the result he obtains shows that at any rate the *reality* of the sun's motion (the value he gets is 10·9 English statute miles per second), and that our present knowledge of the direction of this motion is at any rate approximate.

AN ASCENDING METEOR.—Prof. von Niessl has been investigating the path of the meteor that appeared on July 7, 1892, and was seen both in Austria and Italy. The result of this computation has shown that, undoubtedly, the path of the meteor at the *latter* end of its course (*Naturwissenschaftliche Wochenschrift*, No. 26) was directed upwards. The length of its path measured 1100 kilometres from its nearest approach to the earth surface (68 kilometres above the surface) to the point where it disappeared, which was at a height of 158 kilometres. This is about the first time that the path of a rising meteor has been so accurately investigated.

THE SATELLITES OF JUPITER.—In this column for March 30 of this year we referred briefly to the very important results that were being reaped by Prof. W. H. Pickering, with the help of Mr. Douglas, at Arequipa, with reference to the peculiar forms which the satellites were found to assume at different periods of their rotation. In the June number of *Astronomy and Astro-physics* we have before us a much more detailed account of these and later observations, which seem to have confirmed those made previously in nearly all respects. In this article, which is of some length, the author deals first with the third satellite, the largest and most easily observed of the group. The results of twelve series of observations, taken on seven different nights, each series consisting of six independent observations, gave the value of $-10°·5$ for the position angle of the major axis, the satellite being on the eastern side of its orbit, and presenting an elliptical disc. The observations for the elliptical phase at the western side were not very satisfactory, owing to bad meteorological conditions, but the results suggested that "they would imply a revolution of the axis about the line perpendicular to the orbital plane, in about the same period as the satellites' rotation upon the axis itself." With regard to the surface features, there seems to be a marking having the appearance of a fork, the angle of the prongs varying from 30° to 60°. Sometimes this forked-shaped feature is turned to the left and sometimes to the right, and occasionally a double fork is seen. The position angle of the axis of the belt gave a value of $+15°·5$, and when the values obtained on January 1 and 16 are compared with those attained for the major axis on the same dates, they indicate that the two axis are inclined at between 46° to 35° to one another. The attempt to determine the direction and period of rotation indicated that perhaps the period of rotation coincided with that of the revolution of the satellite in its orbit. The surface features on the first satellite consisted of the bands lying in an approximately north and south direction, that on the second of a small patch detected only upon one occasion, and that on the fourth of a broad band (sometimes a narrow line), and also a bright spot recorded several times at the North Pole and once near the south. Later determinations of the period of rotation of the second satellite confirmed the earlier value (41h. 24m.), but sometimes discrepancies in the time of the flattening of the disc still occurred. The direction and period of rotation of satellite 4 has not been determined, but its disc has been recorded upon fourteen different dates as being shortened in the direction of the plane of its orbit, and upon eleven other days as being circular in form.

After summing up the main facts with regard to these satellites respecting their small density, directions of rotation, changes of shape, &c., Prof. Pickering shows how Laplace's "ring theory" with the following premises, suits the facts:—

(1) Jupiter was formerly surrounded by a series of rings similar to those now surrounding Saturn.

(2) The direction of rotation of these rings was direct, like that of the planet.

(3) By some force, whose cause is not explained, they were shattered, their components uniting, but still retaining the same orbit.

(4) Like the original rings, each satellite still consists of a swarm of meteorites, their consolidation having been prevented by the enormous tides produced in them by their primary.

At the conclusion of this discussion, in which Prof. Pickering takes each point individually, he has drawn up a syllabus regarding the points to which an observer can be most profitably directed in the case of each satellite, subdividing them into grades according to the difficulty of the observations.

TURACIN: A REMARKABLE ANIMAL PIGMENT CONTAINING COPPER.[1]

THE study of natural colouring matters is at once peculiarly fascinating and peculiarly difficult. The nature of the colouring matters in animals and plants, and even in some minerals (ruby, sapphire, emerald, and amethyst, for example) is still, in the majority of cases, not completely fathomed.

Animal pigments are generally less easily extracted and are more complex than those of plants. They appear invariably to contain nitrogen—an observation in accord with the comparative richness in that element of animal cells and their contents. Then, too, much of the colouration of animals, being due to microscopic structure, and therefore having a mechanical and not a pigmentary origin, differs essentially from the colouration of plants. Those animal colours which are primarily due to structure do, however, involve the presence of a dark pigment —brown or black—which acts at once as a foil and as an absorbent of those incident rays which are not reflected.

Many spectroscopic examinations of animal pigments have been made. Except in the case of blood and bile pigments very few have been submitted to exhaustive chemical study. Spectral analysis, when uncontrolled by chemical, and when the influence of the solvent employed is not taken into account, is very likely to mislead the investigator. And, unfortunately, the non-crystalline character of many animal pigments, and the difficulty of purifying them by means of the formation of salts and of separations by the use of appropriate solvents, oppose serious obstacles to their elucidation. Of blood-red or hæmoglobin it cannot be said that we know the centesimal composition, much less its molecular weight. Even of hæmatin the empirical formula has not yet been firmly established. The group of black and brown pigments to which the various melanins belong still await adequate investigation. We know they contain nitrogen (8½ to 13 per cent.), and sometimes iron, but the analytical results do not warrant the suggestion of empirical formulæ for them. The more nearly they appear to approach purity, the freer the majority of them seem from any fixed constituent such as iron or other metal. It is to be regretted that Dr. Krukenberg, to whom we are indebted for much valuable work on several pigments extracted from feathers, has not submitted the interesting substances he has described to quantitative chemical analysis.

I must not, however, dwell further upon these preliminary matters. I have introduced them mainly in order to indicate how little precise information has yet been gathered as to the constitution of the greater number of animal pigments, and how difficult is their study.

And now let me draw your attention to a pigment which I had the good fortune to discover, and to the investigation of which I have devoted I am afraid to say how many years.

It was so long ago as the year 1866 that the solubility in water of the red colouring matter in the wing-feathers of a plantain-eater was pointed out to me. [One of these feathers,

[1] A discourse delivered at the Royal Institution by Prof. A. H. Church, F.R.S.

freed from grease, was shown to yield its pigment to pure water.] I soon found that alkaline liquids were more effective solvents than pure water, and that the pigment could be precipitated from its solution by the addition of an acid. [The pigment was extracted from a feather by very dilute ammonia, and then precipitated by adding excess of hydrochloric acid.] The next step was to filter off the separated colouring matter, and to wash and dry it. The processes of washing and drying are tedious, and cannot be shown in a lecture. But the product obtained was a solid of a dark crimson hue, non-crystalline, and having a purple semi-metallic lustre. I named it "turacin" (in a paper published in a now long defunct periodical, *The Student and Intellectual Observer*, of April, 1868). The name was taken from "Turaco," the appellation by which the plantain-eaters are known—the most extensive genus of this family of birds being *Turacus*.

From the striking resemblance between the colour of arterial blood and that of the red touraco feathers I was led to compare their spectra. Two similar absorption bands were present in both cases, but their positions and intensities differed somewhat. Naturally I sought for iron in my new pigment. I burnt a portion, dissolved the ash in hydrochloric acid, and then added sodium acetate and potassium ferrocyanide. To my astonishment I got a precipitate, not of Prussian blue, but of Prussian brown. This indication of the presence of copper in turacin was confirmed by many tests, the metal itself being also obtained by electrolysis. It was obvious that the proportion of copper present in the pigment was very considerable—greatly in excess of that of the iron (less than ½ per cent.) in the pigment of blood.

Thus far two striking peculiarities of the pigment had been revealed, namely, its easy removal from the web of the feather, and the presence in it of a notable quantity of copper. Both facts remain unique in the history of animal pigments. The solubility was readily admitted on all hands, not so the presence of copper. It was suggested that it was derived from the Bunsen burner used in the incineration, or from some preservative solution applied to the bird-skins. And it was asked, "How did the copper get into the feathers?" The doubters might have satisfied themselves as to copper being normally and invariably present by applying a few easy tests, and by the expenditure of half-a-crown in acquiring a touraco wing. My results were, however, confirmed (in 1872) by several independent observers, including Mr. W. Crookes, Dr. Gladstone, and Mr. Greville Williams. And in 1873 Mr. Henry Bassett, at the request of the late Mr. J. J. Monteiro, pushed the inquiry somewhat further. I quote from Monteiro's "Angola and the River Congo," published in 1875 (vol. ii. pp. 75–77):—"I purchased a large bunch of the red wing-feathers in the market at Sierra Leone, with which Mr. H. Bassett has verified Prof. Church's results conclusively," &c., &c. Mr. Bassett's results were published in the *Chemical News* in 1873, three years after the appearance of my research in the Phil. Trans. As concentrated hydrochloric acid removes no copper from turacin, even on boiling, the metal present could not have been a mere casual impurity; as the proportion is constant in the turacin obtained from different species of touraco, the existence of a single definite compound is indicated. The presence of traces of copper in a very large number of plants, as well as of animals, has been incontestably established. And, as I pointed out in 1868, copper can be readily detected in the ash of banana fruits, the favourite food of several species of the "turacin-bearers." The feathers of a single bird contain on the average two grains of turacin, corresponding to ·14 of a grain of metallic copper; or, putting the amount of pigment present at its highest, just one-fifth of a grain. This is not a large amount to be furnished by its food to one of these birds once annually during the season of renewal of its feathers. I am bound, however, to say that in the blood and tissues of one of these birds, which I analysed immediately after death, I could not detect more than faint traces of copper. The particular specimen examined was in full plumage; I conclude that the copper in its food, not being then wanted, was not assimilated.

Let us now look a little more closely at these curious birds themselves. Their nearest allies are the cuckoos, with which they were formerly united by systematists. It has, however, been long conceded that they constitute a family of equal rank with the Cuculidæ. According to the classification adopted in the Natural History Museum, the order Picariæ contains eight suborders, the last of which, the Coccyges, consist of two families, the Cuculidæ and the Musophagidæ. To the same order belong the Hoopoes, the Trogons, the Woodpeckers. The plantain-eaters, or Musophagidæ, are arranged in six genera and comprise twenty-five species. In three genera—Turacus, Gallirex, and Musophaga—comprising eighteen species, and following one another in zoological sequence, turacin occurs; from three genera (seven species)—Corythæola, Schizorhis, and Gymnoschizorhis—the pigment is absent. [The coloured illustrations to H. Schlegel's Monograph (Amsterdam, 1860) on the Musophagidæ were exhibited.] The family is confined to Africa—eight of the turacin-bearers are found in the west sub-region, one in the south-west, two in the south, two in the south-east, four in the east, two in the central, and two in the north-east. It is noteworthy that, in all these sub-regions save the south-east, turacin-bearers are found along with those plantain-eaters which do not contain the pigment. Oddly enough two of the latter species, *Schizorhis africana* and *S. zonura*, possess white patches destitute of pigment in those parts of the feathers which in the turacin bearers are crimson. These birds do not—I will not say cannot—decorate these bare patches with this curiously complex pigment. [Some extracts were here given from the late Mr. Monteiro's book on Angola, vol. ii. pp. 74–79, and from letters by Dr. B. Hinde. These extracts contained references to curious traits of the Touracos.]

Usually from twelve to eighteen of the primaries or metacarpo-digitals and of the secondaries or cubitals amongst the wing-feathers of the turacin bearers have the crimson patches in their web. Occasionally the crimson patches are limited to six or seven of the eleven primaries. I have observed this particularly with the violet plantain-eater (*Musophaga violacæa*). In these cases the crimson head-feathers, which also owe their colour to turacin, are few in number, as if the bird, otherwise healthy, had been unable to manufacture a sufficiency of the pigment. I may here add that the red tips of the crest-feathers of *Turacus meriani* also contain turacin.

In all the birds in which turacin occurs this pigment is strictly confined to the red parts of the web, and is there unaccompanied by any other colouring matter. It is therefore found that if a single barb from a feather be analysed, its black base and its black termination possess no copper, while the intermediate portion gives the blue-green flash of copper when incinerated in the Bunsen flame. [A parti-coloured feather was burnt in the Bunsen flame with the result indicated.]

Where it occurs turacin is homogeneously distributed in the barbs, barbicels, and crochets of the web, and is not found in granules or corpuscles.

To the natural question, "Does turacin occur in any other birds besides the touracos?" a negative answer must at present be given. At least my search for this pigment in scores of birds more or less nearly related to the Musophagidæ has met with no success. In some of the plantain-eaters (species of Turacus and Gallirex) there is, however a second pigment closely related to turacin. It is of a dull grass-green colour, and was named turacoverdin by Dr. Krukenberg in 1881. I had obtained this pigment in 1868 by boiling turacin with a solution of caustic soda, and had figured its characteristic absorption band in my first paper (Phil. Trans., vol. clix., 1870, p. 630, fig. 4). My product was, however, mixed with unaltered turacin. But Dr. Krukenberg obtained what certainly seems to be the same pigment from the green feathers of *Turacus corythaix* by treating them with a two per cent. solution of caustic soda. I find, however, that a solution of this strength dissolves, even in the cold, not only a brown pigment associated with turacoverdin, but ultimately the whole substance of the web. By using a much weaker solution of alkali (1 part to 1000 of water) a far better result is obtained. [The characteristic absorption band of turacoverdin, which lies on the less refrangible side of D, was shown; also the absorption bands of various preparations of turacin.] I have refrained from the further investigation of turacoverdin, hoping that Dr. Krukenberg would complete his study of it. At present I can only express my opinion that it is identical with the green pigment into which turacin when moist is converted by long exposure to the air, or by ebullition with soda, and which seems to be present in traces in all preparations of *isolated* turacin, however carefully prepared.

A few observations may now be introduced on the physical and chemical characters of turacin. It is a colloid of colloids. And it enjoys in a high degree one of the peculiar properties of colloids—that of retaining when freshly precipitated, an immense proportion of water. Consequently when its solution in am monia is precipitated by an acid, the coagulum formed is very voluminous. [The experiment was shown.] One gram of turacin is capable of forming a semi-solid mass with 600 grams of water. Another character which turacin shares with many other colloids is its solubility in pure water and its insolubility in the presence of mere traces of saline matter. It would be tedious to enumerate all the observed properties of turacin, but its deportment on being heated, and the action of sulphuric acid upon it, demand particular attention.

At 100° C., and at considerably higher temperatures, turacin suffers no change. When, however, it is heated to the boiling-point of mercury it is wholly altered. No vapours are evolved, but the substance becomes black and is no longer soluble in alkaline liquids, nor, when still more strongly heated afterwards can it be made to yield the purple vapours which unchanged turacin gives off under the same circumstances. This peculiarity of turacin caused great difficulty in its analysis. For these purple vapours contain an organic crystalline compound in which both nitrogen and copper are present, and which resists further decomposition by heat. [Turacin was so heated as to show its purple vapours, and also the green flame with which they burn.] This production of a volatile organic compound of copper is perhaps comparable with the formation of nickel and ferro-carbonyl.

The action of concentrated sulphuric acid upon turacin presents some remarkable features. The pigment dissolves with a fine crimson colour and yields a new compound, the spectrum of which presents a very close resemblance to that of hæmatoporphyrin [turacin was dissolved in oil of vitriol; the spectrum of an ammoniacal solution of the turacoporphyrin thus produced was also shown], the product obtained by the same treatment from hæmatin; in other respects also this new derivative of turacin, which I call turacoporphyrin, reminds one of hæmatoporphyrin. But, unlike this derivative of hæmatin, it seems to retain some of its metallic constituent. The analogy between the two bodies cannot be very close, for if they were so nearly related as might be argued from the spectral observations, hæmatin ought to contain not more, but less metal than is found to be present therein.

The percentage composition of turacin is probably carbon 53·69, hydrogen 4·6, copper 7·01, nitrogen 6·96, and oxygen 27·74. These numbers correspond pretty nearly to the empirical formula $C_{82}H_{81}Cu_2N_9O_{32}$; but I lay no stress upon this expression.

I have before said that copper is very widely distributed in the animal kingdom. Dr. Giunti, of Naples, largely extended (1881) our knowledge on this point. I can hardly doubt that this metal will be found in traces in all animals. But, besides turacin, only one organic copper-compound has been as yet recognised in animals. This is a respiratory, and not a mere decorative pigment like turacin. Léon Fredericq discovered this substance, called hæmocyanin. It has been observed in several genera of Crustacea, Arachnida, Gastropoda, and Cephalopoda. I do not think it has ever been obtained in a state of purity, and I cannot accept for it the fantastic formula—$C_{867}H_{1369}CuS_4O_{258}$—which has recently been assigned to it. On the other hand, I do not sympathise with the doubts as to its nature which F. Heim has recently formulated in the *Comptes Rendus*.

It is noteworthy in connection with the periodic law that all the essential elements of animal and vegetable organic compounds have rather low atomic weights, iron, manganese, and copper representing the superior limit. Perhaps natural organic compounds containing manganese will some day be isolated, but at present such bodies are limited to a few containing iron, and to two—hæmocyanin and turacin—of which copper forms an essential part.

If I have not yet unravelled the whole mystery of the occurrence and properties of this strange pigment, it must be remembered that it is very rare and costly, and withal difficult to prepare in a state of assured purity. It belongs, moreover, to a class of bodies which my late master, Dr. A. W. von Hofmann, quaintly designated as "dirts" (a magnificent dirt, truly!)—substances which refuse to crystallise, and cannot be distilled. I have experienced likewise during the course of this investigation, frequent reminders of another definition propounded by the same great chemist when he described organic research as "a more or less circuitous route to the sink"!

I am very glad to have had the opportunity of sharing with an audience in this institution the few glimpses I have caught from time to time during the progress of a tedious and still incomplete research into the nature of a pigment which presents physiological and chemical problems of high, if not of unique, interest.

Let my last word be a word of thanks. I am indebted to several friends for aid in this investigation, and particularly to Dr. MacMunn, of Wolverhampton, the recognised expert in the spectroscopy of animal pigments.

ARTIFICIAL IMMUNITY AND TYPHOID FEVER.

THE announcement by Metchnikoff of his beautiful theory of the "mechanism," as it were, of immunity, which he conceives as dependent upon the activity of the phagocytes or migratory cells of the body in the presence of disease germs, has called forth an immense number of researches in this direction from all parts of the world. But whilst some bacteriologists are engaged upon studying critically the experimental evidence which can be adduced in support of this theory, others are busy with the practical side of the subject and are devoting themselves to the investigation of what substances are capable of conferring immunity upon animals towards any particular disease, and hardly a month passes without some contribution being made to this important inquiry. The great discovery made by Behring that the blood serum of animals rendered artificially immune against a particular disease will, on being introduced into other animals, protect them from an attack of that particular disease, has been confirmed in the case of tetanus or lockjaw by Behring and Kitasato, and as regards diphtheria by Behring. In a more recent contribution Brieger, Kitasato, and Wassermann ("Ueber Immunität und Giftfestigung," *Zeitschrift für Hygiene*, vol. xii. 1892) have, amongst other investigations, succeeded in protecting and healing mice from the evil effects of inoculations with the typhoid bacillus by the introduction of serum obtained from a guinea-pig immune against typhoid. The further study of immunity with reference to this disease is the subject of two elaborate memoirs in the *Annales de l'Institut Pasteur*, November, 1892, by Sanarelli in Siena, and Chantemesse and Widal in Paris, and the ground covered by these two investigations is to a great extent identical. Sanarelli selected guinea-pigs as the subjects for his experiments, these animals being, as is well known, more difficult to protect from the fatal results of typhoid inoculations than mice. He states that if 0·5 c.c. of therapeutic serum be simultaneously introduced with an otherwise fatal dose of a typhoid culture, these animals *without exception* develop no typhoid symptoms, whilst guinea-pigs inoculated with an equally fatal dose of typhoid, but without the curative serum, invariably die. Chantemesse and Widal have pursued the inquiry still further, and have investigated the properties of serum taken from normal animals—that is to say, from animals which have not been infected with or rendered artificially immune from typhoid. Investigations similar to those made previously by Stern have also been conducted with human serum obtained from patients who have recovered from typhoid fever and also from those who have never been attacked by this malady.

Chantemesse and Widal state that whereas the serum derived from typhoid patients and from immune animals invariably confers protection upon infected animals, that obtained from normal animals and from people who have never had typhoid, only exceptionally exercises any curative power. These authors have also compared the degree of immunity induced in animals by the inoculation of curative serum and sterilised cultures of the typhoid bacillus respectively. This latter process is another method of protecting animals against infection, and was resorted to before the experiments with serum were made. It was found that whilst the serum acts rapidly, and confers immunity when administered in small quantities, its protective power only extends over a short period of time, apparently disappearing in less than a month. The sterilised typhoid cultures on the other hand, although working more slowly and requiring to be introduced in larger doses than the serum, endow the animal with immunity over a longer space of time, animals having been found immune even after the lapse of two months. Finally, attempts were made to arrest the progress of typhoid fever in people by the inoculation of therapeutic serum obtained from guinea pigs. So far, however, these investigations have not been successful, and if it be remembered that one point of cardinal importance in the production of immunity or in healing the disease is the time which elapses between the infection and the protective inoculation, that the action of the latter is the more rapid and the more successful the sooner it follows upon the former, it is at once apparent where, at any rate, some of the difficulties lie in its successful application to human beings. Whereas the exact moment is known when the experimental infection in the animal takes place, in the human subject days or weeks may pass between the infection and the declaration of the disease.

THE CENTENARY OF GILBERT WHITE.

THE wonted tranquillity of the little Hampshire village of Selborne was disturbed on Saturday by the invasion of a band of pilgrims who came to look upon the shrine of Gilbert White, and by the sight obtained a renewed love of nature. Drawn by a feeling of regard, members of the Selborne Society, and other disciples of White, congregated from all parts of the country, and paid homage to their master. Never within the memory of the oldest inhabitant had so many people been gathered together at Selborne, and we doubt not that the villagers failed to realise what attraction there could be in a man whose characteristics, according to an old woman who remembered him, were that "he would walk about the lanes tap-tapping at the trees, and stooping every now and then to wipe the dust off his shoes." But one thing marred the enjoyment of Saturday's meeting. A band of gipsies, with a terrible barrel-organ, and all the paraphernalia of a country fair, had installed themselves not a stone's-throw from the house in which Gilbert White lived his peaceful life. And, worst of all, they possessed a steam-syren, the shriek and screech of which penetrated everywhere, even to the high Hangers, in which the Selborne naturalist supposed that swallows hibernated.

The Earl of Selborne presided at luncheon, and, in proposing "The Memory of Gilbert White," dwelt upon the sterling qualities of the man, and the remarkable character of his books dealing with the natural history and antiquities of Selborne. White's life was devoted to observing and recording natural productions and phenomena. He was gifted with shrewdness of discernment, and that one essential qualification of a true man of science—the power of faithfully chronicling all and every observation. It was thought by some that the naturalist whose centenary they were commemorating had nothing else to do but wander about, and observe the habits of birds, beasts, fishes, and insects; but that was a great mistake. He had to perform "the daily round, the common task" that falls to the lot of all, and diligently did he fulfil his duties.

Mr. Darwin proposed "Prosperity to the Selborne Society and its branches." In responding, Mr. Otter, one of the founders of the society, dwelt upon the fact that their object was to inculcate and foster a love of nature, and to wage war in defence of her beauties. To them the ruthless field-naturalist and the sporting collector of specimens were enemies.

Mr. Wakefield followed with a description of the good work done by the Thames Valley branch in preserving "beauty-spots" from jerry-builders and their kindred.

The Earl of Stamford, in proposing "Prosperity to the Hampshire Field Club," the members of which joined the London party at Selborne, remarked that he had found reason to believe that one of the figures shown in the quarto edition of White's book is a likeness of the author himself, hence it could no longer be said that no portrait of him was in existence. Mr. R. H. White, however, was of the opinion that the evidence was not of a positive character.

The question of a memorial to White was touched by the Earl of Selborne, but he thought that the best plan would be to "Look not on the picture, but the book," and leave that to be handed down to the end of time, for nothing more was needed to perpetuate the memory of the man. With this sentiment we by no means agree. A monument is not erected merely to prevent a man's name and deeds from sinking to oblivion. It should show to the people that he was one whom men delight to honour. We are apt to be far too prosaic in these matters, and to consider the raising of images and other memorials as more or less unnecessary conventionalities. This conviction has grown upon us because we have seen statues erected to comparatively obscure individuals time without number, while the works of men of science are unrecognised. It does not say much for the naturalists of this country if the centenary of Gilbert White is allowed to pass without some tangible illustration being given of their regard for the father of them all.

INTERFERENCE BANDS AND THEIR APPLICATIONS.[1]

THE formation of the interference bands, known as Newton's rings, when two slightly curved glass plates are pressed into contact, was illustrated by an acoustical analogue. A high-pressure flame B (Fig. 1) is sensitive to sounds which reach it in the direction EB, but is insensitive to similar sounds which reach it in the nearly perpendicular direction AB. A is a "bird-call," giving a pure sound (inaudible) of wave-length (λ) equal to about 1 cm.; C and D are reflectors of perforated zinc. If C acts alone, the flame is visibly excited by the waves reflected from it, though by far the greater part of the energy is transmitted. If D, held parallel to C, be then brought into action, the result depends upon the interval between the two partial reflectors. The reflected sounds may co-operate, in which case the flame flares vigorously; or they may interfere, so that the flame recovers, and behaves as if no sonnd at all were falling upon it. The first effect occurs when the reflectors are close together, or are separated by any multiple of $\frac{1}{2}\sqrt{2}.\lambda$; the

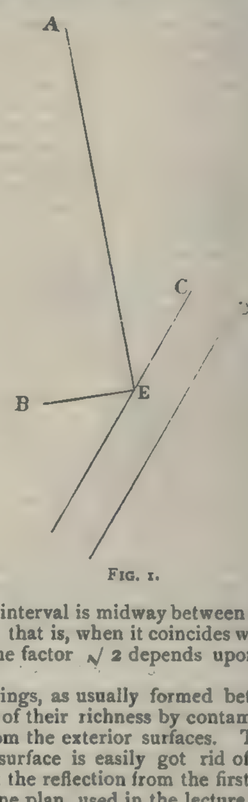


FIG. 1.

second when the interval is midway between those of the above-mentioned series, that is, when it coincides with an odd multiple of $\frac{1}{4}\sqrt{2}.\lambda$. The factor $\sqrt{2}$ depends upon the obliquity of the reflection.

The coloured rings, as usually formed between glass plates, lose a good deal of their richness by contamination with white light reflected from the exterior surfaces. The reflection from the hindermost surface is easily got rid of by employing an opaque glass, but the reflection from the first surface is less easy to deal with. One plan, used in the lecture, depends upon the use of slightly wedge-shaped glasses (2°) so combined that the exterior surfaces are parallel to one another, but inclined to the interior operative surfaces. In this arrangement the false light is thrown somewhat to one side, and can be stopped by a screen suitably held at the place where the image of the electric arc is formed.

The formation of colour and the ultimate disappearance of the bands as the interval between the surfaces increases, depends upon the mixed character of white light. For each colour the bands are upon a scale proportional to the wave-length for that colour. If we wish to observe the bands when the interval is

[1] Abstract of a lecture delivered at the Royal Institution, on Friday, March 24, 1893, by Lord Rayleigh.

considerable—bands of high interference as they are called—the most natural course is to employ approximately homogeneous light, such as that afforded by a soda flame. Unfortunately, this light is hardly bright enough for projection upon a large scale.

A partial escape from this difficulty is afforded by Newton's observations as to what occurs when a ring system is regarded through a prism. In this case the bands upon one side may become approximately achromatic, and are thus visible to a tolerably high order, in spite of the whiteness of the light. Under these circumstances there is, of course, no difficulty in obtaining sufficient illumination; and bands formed in this way were projected upon the screen.[1]

The bands seen when light from a soda flame falls upon nearly parallel surfaces have often been employed as a test of flatness. Two flat surfaces can be made to fit, and then the bands are few and broad, if not entirely absent; and, however the surfaces may be presented to one another, the bands should be straight, parallel, and equi-distant. If this condition be violated, one or other of the surfaces deviates from flatness. In Fig. 2, A and B represent the glasses to be tested, and C is a lens of two or three feet focal length. Rays diverging from a soda flame at E are rendered parallel by the lens, and after reflection from the surfaces are re-combined by the lens at E. To make an observation, the coincidence of the radiant point and its image must be somewhat disturbed, the one being displaced to a position a little beyond, and the other to a position a little in front of, the diagram.

The eye, protected from the flame by a suitable screen, is placed at the image, and being focused upon AB, sees the field traversed by bands. The reflector D is introduced as a matter of convenience to make the line of vision horizontal.

FIG. 2.

These bands may be photographed. The lens of the camera takes the place of the eye, and should be as close to the flame as possible. With suitable plates, sensitised by cyanin, the exposure required may vary from ten minutes to an hour. To get the best results, the hinder surface of A should be blackened, and the front surface of B should be thrown out of action by the superposition of a wedge-shaped plate of glass, the intervening space being filled with oil of turpentine or other fluid having nearly the same refraction as glass. Moreover, the light should be purified from blue rays by a trough containing solution of bichromate of potash. With these precautions the dark parts of the bands are very black, and the exposure may be prolonged much beyond what would otherwise be admissible.

The lantern slides exhibited showed the elliptical rings indicative of a curvature of the same sign in both directions, the hyperbolic bands corresponding to a saddle-shaped surface, and the approximately parallel system due to the juxtaposition of two telescopic "flats," kindly lent by Mr. Common. On other plates were seen grooves due to rubbing with rouge along defined track, and depressions, some of considerable regularity, obtained by the action of diluted hydrofluoric acid, which was allowed to stand for some minutes as a drop upon the surface of the glass.

By this method it is easy to compare one flat with another, and thus, if the first be known to be free from error, to determine the errors of the second. But how are we to obtain and verify a standard? The plan usually followed is to bring *three* surfaces into comparison. The fact that two surfaces can be made to fit another in all azimuths proves that they are spherical and of equal curvatures, but one convex and the other concave, the case of perfect flatness not being excluded. If A and B fit another, and also A and C, it follows that B and C must be similar. Hence, if B and C also fit one another, all three surfaces must be flat. By an extension of this process the errors of three surfaces which are not flat can be found from a consideration of the interference bands which they present when combined in three pairs.

But although the method just referred to is theoretically complete, its application in practice is extremely tedious, especially when the surfaces are not of revolution. A very simple solution of the difficulty has been found in the use of a free surface of water, which, when protected from tremors and motes, is as flat as can be desired.[1] In order to avoid all trace of capillary curvature it is desirable to allow a margin of about $1\frac{1}{2}$ inch. The surface to be tested is supported horizontally at a short distance ($\frac{1}{10}$ or $\frac{1}{20}$ inch) below that of the water, and the whole is carried upon a large and massive levelling stand. By the aid of screws the glass surface is brought into approximate parallelism with the water. In practice the principal trouble is in the avoidance o tremors and motes. When the apparatus is set up on the floor of a cellar in the country, the tremors are sufficiently excluded, but care must be taken to protect the surface from the slightest draught. To this end the space over the water must be enclosed almost air-tight. In towns, during the hours of traffic, it would probably require great precaution to avoid the disturbing effects of tremors. In this respect it is advantageous to diminish the thickness of the layer of water; but if the thinning be carried too far, the subsidence of the water surface to equilibrium becomes surprisingly slow, and a doubt may be felt whether after all there may not remain some deviation from flatness due to irregularities of temperature.

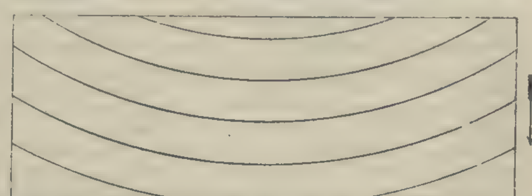

FIG. 3.

With the aid of the levelling screws the bands may be made as broad as the nature of the surface admits; but it is usually better so to adjust the level that the field is traversed by five or six approximately parallel bands. Fig. 3 represents bands actually observed from the face of a prism. That these are not straight, parallel, and equi-distant is a proof that the surface deviates from flatness. The question next arising is to determine the direction of the deviation. This may be effected by observing the displacement of the bands due to a known motion of the levelling screws; but a simpler process is open to us. It is evident that if the surface under test were to be moved downwards parallel to itself, so as to increase the thickness of the layer of water, every band would move in a certain direction, viz. *towards* the side where the layer is thinnest. What amounts to the same, the retardation may be increased, without touching the apparatus, by so moving the eye as to *diminish* the obliquity of the reflection. Suppose, for example, in Fig. 3, that the movement in question causes the bands to travel downwards, as indicated by the arrow. The inference is that the surface is concave. More glass must be removed at the ends of the bands than in the middle in order to straighten them. If the object be to correct the errors by local polishing operations

[1] The theory is given in a paper upon "Achromatic Interference Bands," *Phil. Mag.*, August 1889.

[1] The diameter would need to be 4 feet in order that the depression at the circumference, due to the general curvature of the earth, should amount to $\frac{1}{20}\lambda$.

upon the surface, the rule is that *the bands, or any parts of them, may be rubbed in the direction of the arrow.*

A good many surfaces have thus been operated upon; and although a fair amount of success has been attained, further experiment is required in order to determine the best procedure. There is a tendency to leave the marginal parts behind; so that the bands, though straight over the greater part of their length, remain curved at their extremities. In some cases hydrofluoric acid has been resorted to, but it appears to be rather difficult to control.

The delicacy of the test is sufficient for every optical purpose. A deviation from straightness amounting to $\frac{1}{10}$ of a band interval could hardly escape the eye, even on simple inspection. This corresponds to a departure from flatness of $\frac{1}{20}$ of a wave-length in water, or about $\frac{1}{30}$ of the wave-length in air. Probably a deviation of $\frac{1}{100}\lambda$ could be made apparent.

For practical purposes a layer of moderate thickness, adjusted so that the two systems of bands corresponding to the duplicity of the soda line do not interfere, is the most suitable. But if we wish to observe bands of high interference, not only must the thickness be increased, but certain precautions become necessary. For instance, the influence of obliquity must be considered. If this element were absolutely constant, it would entail no ill effect. But in consequence of the finite diameter of the pupil of the eye, various obliquities are mixed up together, even if attention be confined to one part of the field. When the thickness of the layer is increased, it becomes necessary to reduce the obliquity to a minimum, and further to diminish the aperture of the eye by the interposition of a suitable slit. The effect of obliquity is shown by the formula

$$2t(1 - \cos\theta) = n\lambda.$$

The necessary parallelism of the operative surfaces may be obtained, as in the above-described apparatus, by the aid of levelling. But a much simpler device may be employed, by which the experimental difficulties are greatly reduced. If we superpose a layer of water upon a surface of mercury, the flatness and parallelism of the surfaces take care of themselves. The objection that the two surfaces would reflect very unequally may be obviated by the addition of so much dissolved colouring matter, *e.g.* soluble aniline blue, to the water as shall equalise the intensities of the two reflected lights. If the adjustments are properly made, the whole field, with the exception of a margin near the sides of the containing vessel, may be brought to one degree of brightness, being, in fact, all included within a fraction of a band. The width of the margin, within which rings appear, is about one inch, in agreement with calculation founded upon the known values of the capillary constants. During the establishment of equilibrium after a disturbance, bands are seen due to variable thickness, and when the layer is thin, persist for a considerable time.

When the thickness of the layer is increased beyond a certain point, the difficulty above discussed, depending upon obliquity, becomes excessive, and it is advisable to change the manner of observation to that adopted by Michelson. In this case the eye is focused, not, as before, upon the operative surfaces, but upon the flame, or rather upon its image at E (Fig. 2). For this purpose it is only necessary to introduce an eye-piece of low power, which with the lens C (in its second operation) may be regarded as a telescope. The bands now seen depend entirely upon obliquity according to the formula above written, and therefore take the form of circular arcs. Since the thickness of the layer is absolutely constant, there is nothing to interfere with the perfection of the bands except want of homogeneity in the light.

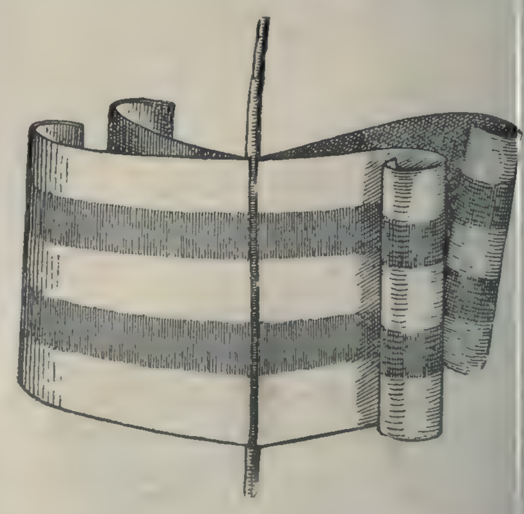
But, as Fizeau found many years ago, the latter difficulty soon becomes serious. At a very moderate thickness it becomes necessary to reduce the supply of soda, and even with a very feeble flame a limit is soon reached. When the thickness was pushed as far as possible, the retardation, calculated from the volume of liquid and the diameter of the vessel, was found to be 50,000 wave lengths, almost exactly the limit fixed by Fizeau.

To carry the experiment further requires still more homogeneous sources of light. It is well known that Michelson has recently observed interference with retardations previously unheard of, and with the aid of an instrument of ingenious construction has obtained most interesting information with respect to the structure of various spectral lines.

A curious observation respecting the action of hydrofluoric acid upon polished glass surfaces was mentioned in conclusion. After the operation of the acid the surfaces appear to be covered with fine scratches, in a manner which at first suggested the idea that the glass had been left in a specially tender condition, and had become scratched during the subsequent wiping. But it soon appeared that the effect was a *development* of scratches previously existent in a latent state. Thus parallel lines ruled with a knife edge, at first invisible even in a favourable light, became conspicuous after treatment with acid. Perhaps the simplest way of regarding the matter is to consider the case of a furrow with perpendicular sides and a flat bottom. If the acid may be supposed to eat in equally in all directions, the effect will be to *broaden* the furrow, while the depth remains unaltered. It is possible that this method might be employed with advantage to *intensify* (if a photographic term may be permitted) gratings ruled upon glass for the formation of spectra.

FROST FREAKS.

MR. LESTER F. WARD describes some remarkable frost figures in the current number of *The Botanical Gazette*. He says that on a bright frosty morning in December, 1892, Mr. Victor Mason and himself observed some white objects looking like icicles close to the ground, along the border of a pine wood. A closer examination showed that they were in truth nothing but ice, but that instead of icicles they were veritable freaks of frost. Every one was firmly attached to the stem of a small herbaceous plant which had succumbed to the season but still stood erect. The attachment was always close to the base, often at the very ground, sometimes an inch above. At a distance, the frost-works had the appearance of cylindrical masses, but one need not come very near to see that such was not the case. In fact, they really consisted of several thin foils or wings from one to three inches in width, firmly attached by one edge to the stem of the plant, thus standing in a vertical position.



From this attachment each of these little ice sheets projected out horizontally or with a slight upward tendency, not straight and stiff, but gently and gracefully curving or coiling into a beautiful conch-like roll at the distal margin. There were always several of these, usually three, four, or five, all attached to the same vertical portion of the stem but at regular intervals around it like the paddles of a flutter-wheel, but all curving in the same direction after the manner of a turbine-wheel. Thus, where there were four they stood with each pair opposite, as in the figure, which represents a side view. The amount of curving varied considerably, and the coil filled up most of the interval between the plates giving the object a compact appearance. The ice was white, opaque, and singularly light, as if consisting of congealed froth, but in all cases the scrolls bore horizontal stripes like those of a flag, resulting from degrees in the whiteness, varying from alabaster to nearly transparent. These stripes added greatly to the beauty of these singular objects. In some cases the inner margin, instead of being straight, was sinuous, giving a fluted character to the base of the wing. Many other peculiarities were noted in these evanescent toys, but they soon vanished.

But here is the chief wonder. There grew in the same situation some dozen or twenty small herbaceous plants of about the same general character which would all seem equally liable to exhibit such a phenomenon. There were species of Aster, Solidago, Chrysopsis, Pycnanthemum, Polygonum, Ludwigia, Sericocarpus, &c., and with these in considerable but not specially marked abundance, *Cunila Mariana.* The first frost-works seen were attached to this plant, which was supposed for a while to be an accident; but soon it was perceived that such was not the case, and an examination of hundreds of cases revealed the fact that they were exclusively confined to this species. No sign or semblance of them could be found on any other plant. They were, therefore, so far as observation went, a specific character, and it is this alone which prompted Mr. Ward to give the above account in the hope that others might be able to confirm or invalidate this induction by a wider one.

This plant persists after frost with all its branches, sere leaves, and empty seed vessels intact, so that its identity was as complete as in midsummer. The bark, which remained firm everywhere else, was seen to be longitudinally split into strips at the zone occupied by the frost-work, but as it could be seen between the several ice sheets, these rifts must have been covered by their bases. In other words, it cannot be doubted that the liquid matter out of which they were formed had passed through these longitudinal openings and been deposited by molecular accretions in the symmetrical forms observed. It was inferred from this that they might consist entirely of the juices of the plant, but on placing them on the tongue nothing distinguishable from pure distilled water could be detected. As the upper part of the stems was dead and dry and the roots perennial, the conclusion was that the water had by some agency been pressed or drawn up through the cambium layer of the roots from the soil and forced out through these apertures in the bark. The action of frost in the ground might account for the required pressure, and the whole would be thus explainable on physical principles. But it explains too much, since no reason can be assigned why the phenomenon should not be universal and not confined to a single species.

Since making these observations Mr. Ward has been to some pains to ascertain whether the phenomenon has been witnessed by others, but so far the inquiry has proved futile. It seems possible, therefore, that this is the first time that *Cunila Mariana* has been discovered to be a frost-weed. *Helianthemum Canadense*, however, behaves in a similar way. That plant is not common in the dittany and there has not been an opportunity to observe it at the proper season. The statement in the first edition of Gray's Manual, 1848, where the name "frost weed" is given to this species, that "late in autumn crystals of ice shoot from the cracked bark at the root, whence the popular name," repeated in all subsequent editions and copied into many other books, is doubtless founded on earlier recorded observations, but is not found in Nuttall or Pursh. A frost-figure also appears in Mr. Wm. Hamilton Gibson's recent book entitled "Sharp Eyes."[1] This figure is somewhat fanciful, being a vignette constituting the first letter of this chapter of his book and aiming to show all the parts of the plant in addition to the frost work. Although it is, according to this representation, a much less definite and less beautiful object than the dittany "frost-flowers," there can be no doubt that the principle on which it was formed is the same. The author's description of it as "fashioned into all sorts of whimsical feathery curls and flanges and ridges" indicates at once the inadequacy of his figure to do it justice, and the close analogy between it and the "frost flower" of Cunila.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

PROF. JEBB, M.P., in presenting the prizes and certificates on Tuesday to the students who successfully passed the last Cambridge local examination at Eastbourne centre, observed that thirty years ago examinations were believed to be a panacea for every educational defect. Now a reaction had set in, and some went so far as to hold that success in examinations afforded no trustworthy criterion of merit. The truth, of course, lay between these two extremes. An examination was not an infallible test, and was more favourable to some temperaments than to others; but, when well managed, was a sound test. An examiner must have at least three qualifications: he must know a great deal more than the subject in which he examined, or he would not have a proper sense of intellectual proportion and perspective; he must have a certain measure of acuteness to enable him to penetrate disguise or simulated knowledge; and, above all, he must have common sense in order to take proper account of particular circumstances of each case. The two older Universities, in the early part of the century, were said to be no longer in touch with the nation, and were regarded rather as great schools reserved for the education and, equally perhaps, the amusement of a select few; but now they had spread a network of examination, and were diffusing their influence over the country, becoming what they were in the Middle Ages, really national, but national in the higher sense, in the desire that every one who sought it should have the means of a liberal education, and that the best things which literature or science had to show should be placed within reach of all.

MR. ROBERT HOLT, late Assistant Lecturer in Engineering at University College, Liverpool, has been appointed Professor of Engineering at the People's Palace, London. Mr. Holt has held both Whitworth and National Scholarships, as well as one of the research scholarships founded by the Commissioners of the Exhibition of 1851.

AT a council meeting of the University College of Wales, Bangor, on June 21, a scheme for the supervision and residence of women students of the college next session was carried by a large majority.

LORD HERSCHEL has been appointed to succeed the late Earl of Derby as Chancellor of the University of London.

OXFORD has conferred the degree of D.C.L. upon Sir John B. Lawes, Bart., F.R.S.

SCIENTIFIC SERIAL.

Meteorologische Zeitschrift, May.—Rainfall probability and cloud in the United States, by W. Köppen. The author has submitted the rainfall charts published by the United States Government to a thorough investigation. The following are the generalised results as regards the distribution of rainfall:—(1) There is a district of continental summer rains, enclosed on both sides by littoral winter rains, which, corresponding to the contrast of the yearly oscillation of temperature, are much more marked in the west than in the east. (2) A district of isobaric summer rains, in the south-east, with equatorial sea-winds in summer, and with anticyclonic weather in winter. (3) Transition districts, in which both rainfall maxima occur near each other, while the minima occur in spring and autumn. Maxima after the equinoxes are nowhere very well marked, but the April and May rains of Colorado and Kansas and the autumn rains on Lake Superior are indications of them. With regard to the seasonal distribution in the tropical zone, the differences of temperature play only a small part compared to that of extra-tropical regions; this result naturally follows from the small variation of temperature in the tropics.—On the dynamics of the atmosphere, by M. Möller. This first part deals chiefly with the causes of the inversion of temperature with height, and with the cold experienced in the centres of areas of high barometric pressure. He deals especially with three causes of inversion:—The cooling of the lower strata by radiation, the effects on the higher strata by dynamic heating or cooling analogous to those caused by the action of Föhn winds, and the transference of warm air to the higher regions by horizontal winds coming from warmer parts. Various cases are separately considered from data afforded by mountain stations, such as Ben Nevis, and from discussions by Dr. Hann and others. Particular attention is also given to the formation and motions of clouds, as furnishing visible evidence of the processes in action in the higher strata of the atmosphere.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 8.—"Preliminary Report of the Joint Solar Eclipse Committee of the Royal Society, the Royal Astronomical Society, and the Solar Physics Committee on the

[1] New York, 1892. Article "The Frost Flower," pp. 210, 211.

Observations of the Solar Eclipse of April 16, 1893." Communicated by Dr. Common, F.R.S.

This report merely states the work undertaken by the British observers during the recent total solar eclipse, and the number and kind of photographs that were obtained. This information has appeared, from time to time, in these columns. A more detailed report, giving the results of the discussion of the pictures will shortly be published.

PARIS.

Academy of Sciences, June 12.—M. Lœwy in the chair.—Experimental verifications of the theory of weirs without lateral contraction, the sheet being free below, by M. J. Boussinesq.—On a simplification introduced into certain formulæ depending upon the resisting power of solids by introducing the greatest linear extension Δ which can be supported by the material, in the place of the corresponding elastic force R_0, by M. J. Boussinesq. In formulæ relating to the strength of elastic solids in motion, mechanicians as a rule introduce a quantity R_0 denoting the greatest tension which a fibre can sustain upon unit sectional area without breaking, instead of the maximum elongation Δ which does not endanger the texture. M. Boussinesq shows that many formulæ may be considerably simplified by introducing Δ. Thus the maximum velocity V which can be safely impressed upon an element of a solid under concussion is related to the velocity of sound in the solid and to Δ in a manner given by the formula $V = k\omega\Delta$, where k is a constant depending on the figure and mass of the solid, and ω is the velocity of sound in it. If V be the peripheral velocity of a flywheel in the form of a narrow ring with a large radius, the maximum safe velocity is given by the formula $V = \omega\sqrt{\Delta}$.—On various methods of observing the so-called anomalous focal properties of diffraction gratings, by M. A. Cornu.—On the extraction of zirconia and thorina, by M. L. Troost.—Study of some new phenomena of fusion and volatilisation produced by means of the heat of the electric arc, by M. Henri Moissan.—On Liouville's linear element surfaces, and surfaces with constant curvature, by M. Émile Waelsch.—On a general property of electric and magnetic fields, by M. Vaschy.—Study of the filtration of liquids, by M. R. Lezé. A porous vessel containing the liquid to be studied was placed in a test-tube and subjected to very rapid rotation. By a comparison of the weights of the porous vessel and its contents before and after rotation, the velocity of outflow through the porous walls due to centrifugal force was ascertained. Taking that of distilled water as unity, the figure for a five per cent. solution of sodium chloride was 1·023, for the nitrate 1·051, for ammonium sulphate 0·993. The velocity of efflux for alcohol solution showed a minimum at 40°, where it was 0·50. The numbers are those for a pressure of eight or ten atmospheres applied during ten minutes, during which the tubes travelled from 40 to 50 km.—On the combinations of molybdates and sulphurous acid, by M. E. Péchard.—On bromine-boracites; bromine compounds of iron and zinc, by MM. G. Rousseau and H. Allaire.—On fluorides of copper, by M. Poulenc.—Action of electricity upon the carburisation of iron by cementation, by M. Jules Garnier.—On the rotatory power of bodies belonging to an homologous series, by M. Ph. A. Guye. It is shown theoretically that if the schematic tetrahedron is slightly deformed, the rotatory powers of a homologous series of bodies must pass through a maximum.—On the rotatory powers of the ethers of valeric and glyceric acids, by MM. Ph. A. Guye and L. Chavanne. This paper contains experimental evidence supporting the conclusions of the previous paper.—Heat of formation of some derivatives of indigo, by M. R. d'Aladern.—On right-handed licareol, by M. Ph. Barbier.—A new apparatus for measuring the intensity of perfumes, by M. Eugène Mesnard. The instrument is based upon the property of essence of terebenthine of extinguishing the phosphorescence of phosphorus when mixed with the surrounding air in a certain minimum proportion. The phosphorescent body is a small piece of starch dipped into a concentrated solution of phosphorus in carbon bisulphide. After once determining the quantity of essence necessary to extinguish phosphorescence, the quantity of essence contained in air may be ascertained by passing sufficient of the air through the apparatus to produce extinction. This air is mixed with other air containing a known quantity of the essential oil or other perfume to be examined, and the odoriferous power of the latter is given by the quantity required to produce a "neutral" scent.—On the fertilisation of the Puccinicei, by M. Paul Vuillemin.—Magnesian chalk of the environs of Guise (Aisne), by M. H. Boursault.—On the cavern of Boundoulaou (Aveyron), by MM. E. A. Martel and Émile Rivière.—On the utilisation of the waste products of the vineyard, by M. A. Muntz.—Mode of action of the substances produced by microbes upon the circulatory apparatus, by MM. Charrin and Gley.—On a soluble derivative of β-naphthol, by MM. Dujardin-Beaumetz and Stackler.—On morbid intercurrencies in sulphate of quinine fevers, by M. Alcide Treille.

THURSDAY, JULY 6, 1893.

THE GREAT BARRIER REEF OF AUSTRALIA.

The Great Barrier Reef of Australia; its Products and Potentialities. By W. Saville-Kent, F.L.S., F.Z.S., F.I.Inst. 387 pp., 64 pls. (London: W. H. Allen and Co., Limited.)

THE first thought that strikes one in glancing through this magnificently illustrated volume is the diligence and skill of the author in photography and the enterprise of the publisher. Never before has a semi-scientific work been illustrated with such a wealth of plates. The illustrations will go far towards giving a realistic impression of some of the beauties of coral seas to the untravelled, and will awaken many recollections of happy hours of exciting shore collecting in those who have waded on coral reefs and peered over a boat-side at the edge of a reef.

The objects of the author in writing this book are set down in the Preface as being manifold—primarily to place before the reading public generally, and the scientific world in particular, more extensive and accurate information about coral-reefs as represented by the largest existing coral structure. Another prominent purpose is to lead to the industrial development of the "marvellous resources" of the Great Barrier Reef.

The book commences with a detailed description of over forty photographs of reefs and corals. These will well repay careful study, and to some naturalists they will be the most valuable portion of the work. The illustrations are unique for beauty, truthfulness, and number, and the descriptions are short and to the point. Two photographic plates and three sketches illustrate some groups of corals on the reef at Vivien Point, Thursday Island, of which measurements are given to furnish some data concerning the average rate of growth of the more important reef-forming species. The numerous plates of reef-scapes may possibly give the impression that coral reefs always present such scenes of interest and beauty, but the reader must be warned that it is only at low spring tides that he will see reefs as here photographed. At ordinary low tide the exposed surface of a reef is ugly and comparatively uninteresting. The amount of exposure to the fierce rays of a tropical sun which some corals can withstand will be surprising to many zoologists. In a few cases a future zoologist will be able to compare the *ad interim* growth or modification of a reef by the landmarks which appear in certain of Mr. Saville-Kent's photographs; but, unfortunately, little information of this kind is given, and it is still more to be regretted that the aspect of the area photographed is not recorded, there being no indication whether it is on the side of the steady south-east trade-wind or subject to the calms and storms of the north-west monsoon. It would further be of great interest if one knew why one reef or portion of a reef consisted almost solely of the genus Madrepora, while Porites characterises another area, or mixed corals a third.

The general reader is provided with the indispensable account of coral reefs, their general structure and theories of origin. This consists largely of appropriate quotations from other writers.

The third chapter is devoted "to a consideration of the general structure and most probable mode of origin of the Great Barrier Reef of Australia," the more notable features of the reef being described in order, beginning with the most southerly end. The view is enunciated "that coral-reefs are produced in the tropics, not with relation so much to the intrinsic reef-constructing properties of the specific coral polyps, but with relation to the rule that reef consolidation (or the amalgamation of coral *débris* into a more or less solid, coarse or fine, concrete, or into a finer-grained, compact limestone) is associated only with the rapid evaporation of the lime-saturated sea-water on inter-tropical, tidally exposed, coral banks or beaches." The presence of dead specimens of reef corals in Moreton Bay suggests two questions. Why did they not form reefs or reef-rock when they were abundant? and why have they now all but become extinct? Mr. Saville-Kent answers the first question by suggesting that the temperature of Moreton Bay is insufficient to produce the requisite rapid evaporation, and the second by pointing out that the increasing size of the three large islands which hem in the bay has latterly tended to freshen the bay in flood time, and this has led to the destruction of the corals. In his description of the Great Barrier Reef Mr. Saville-Kent has quoted largely from Jukes' "Voyage of the *Fly*" and thus endorses the accuracy of the observations of that distinguished naturalist. With regard to the question of subsidence and elevation, Mr. Saville-Kent found at many stations throughout the Barrier region (notably at Albany Pass, Cape York) large expanses of dead brittle coral *in situ* between high-water mark and the living banks. These beds of dead coral are now exposed to atmospheric influences which are antagonistic to coral growth with every ordinary springtide, and hence he concludes the general upheaval of the area on which it grew; additional evidence is given from the shallowing of a bay in Magnetic Island, near Townsville.

"It is difficult," Mr. Saville-Kent adds, "to associate the phenomena described in the foregoing record with any other than a movement of upheaval; but, accepting this as proven, and premising for the nonce that the whole length and breadth of the Barrier region exhibited a similar testimony of emergence, the amount raised, a foot or two only, would be as nothing compared with the latitude of movement in one direction or the other that is required to account for the construction of the Barrier's mass. Had the Great Barrier been fashioned during a prolonged epoch of upheaval, substantial evidence of such movement would be yielded by the strata of the seaboard which it skirts; but of this there is virtually none." Thus Mr. Saville-Kent supports the conclusion arrived at by Prof. Jukes and by the Reviewer that this is not an area of recent elevation. Mr. Saville-Kent refers to the well-known fact that all of the few big breaches in the Barrier's outer rampart are opposite large estuaries, though at the present time too remote from them to be influenced by their streams. These are to be expected on the subsidence hypothesis. Mr. Saville-Kent further elaborates an argument for this theory on the fauna of Tasmania and New Guinea being essentially similar to that of the respective neighbouring coasts of Australia and a more remote connection between New Zealand and Queensland through "Wallace's Bank." Mr. C. W. De Vis has recently identified some fossil bird bones from the Darling Downs (Queensland) as belonging to a true Moa (*Dinornis Queenslandiæ* n.sp.) to an allied genus (*Dromornis* n.g.) and to a near ally of the Kiwi (*Metapteryx bifrons* g.sp. nn.). This discovery is of such importance that it requires corroboration before it can be finally accepted by zoologists. It is unfortunate that on p. 137 occurs a foot-note in which the native name of an island in Torres Straits, "Moa," is associated with that of the extinct New Zealand bird. On the preceding page Dr. Wallace is quoted as saying that the complete disseverance of Australia and New Zealand was probably in the earlier portion of the tertiary period at least, and previous to this Mr. Saville-Kent himself says that "the very conspicuous racial distinctions between the human inhabitants of New Guinea, the Torres Strait Islands, and the Australian Continent, indicate that the separation of the districts must have been accomplished in prehistoric times, probably in a middle tertiary epoch."

While this statement of Mr. Saville-Kent's disproves his own suggestion, it cannot pass unchallenged. The Torres Straits Islanders are Papuans with probably, in some cases, an admixture of North Queensland blood, but anyhow, migration across Torres Straits is easy enough and does not require a land connection.

"Corals and Coral Animals" have a chapter to themselves. The classification adopted is not to be commended, and the term Zoantharia is restricted to the Zoantheæ, contrary to universal usage. Several new species of Actiniaria are described in general terms, and one new genus, *Physobrachia*, is erected for a polyp having "bladder-like apices of the tentacles." There is no evidence to show that this is a sea-anemone at all. The most remarkable form collected by Mr. Saville-Kent is a zoanthean which grows on an erect zigzag tube, about which there is a division of opinion; some zoologists regard it as an example of commensalism between an unknown annelid and a zoanthus, but Mr. Saville-Kent believes that the tube is secreted by the zoanthean, which he names *Acrozoanthus Australiæ*. The Reviewer finds that anatomically and histologically the polyp agrees precisely with other species of the genus Zoanthus. A rough sketch is given of *Platyzoanthus mussoides* Nov. gen. n.sp. which is insufficient for accurate determination; this is almost certainly a Hexactinian and not a Zoanthean, and probably it is *Rhodactis bryoides* H. and S., or an allied species. The section on the Madreporaria, or stony corals, is excellent, and the photographic illustrations of expanded corals are very valuable. The colours of the different species are described, and attention is drawn to the fact that not only may the same species, but in one case even the same individual varies in colour. The description of the Alcyonaria is valuable when confined to observations on the reef.

The chapter on "Pearl and Pearl-shell Fisheries" is chiefly intended for those interested in the commercial aspects of this important fishery, the average annual value of which is stated to be £69,000. The profits of the fishery are made out of the pearl-shell only, for though pearls, and often very valuable ones too, are frequent, they largely form the illegal perquisites of the nati crews. Mr. Saville-Kent distinguishes two species, t large white shell *Meleagrina margaritifera* and a small black-edged form which he names *M. nigro-marginat* Mr. Saville-Kent has proved that it is possible to tran plant living pearl-shell, and his experiments open up prospect of the "shellers," as they are locally terme forming nursery beds to which undersized shell can transferred to be again taken up when they are bett grown. The shells from these beds could be open under the superintendence of the owners, who would th secure the pearls. The author is inclined to think th under favourable conditions a period not exceeding thr years suffices for the shell to attain to the marketab size of eight or nine inches in diameter, and that hea shells of 5lb. or 6lb. weight per pair may be the produ of five years' growth.

The account of the "Bêche-de-Mer Fisheries" is o of the most workmanlike sections of the book. For t first time we can associate such terms as "prickly re or "teat fish" with their appropriate scientific name Twenty species of Holothurians are popularly diagnose of which six are described as being new species. only the fully-grown forms are found on the surface the reefs there is little fear of extermination throu over-fishing.

A long chapter is devoted to "Oysters and Oyst Fisheries of Queensland," which is of more local a commercial than of general interest. Several speci and numerous varieties of Ostrea are described a figured.

Two coloured plates and six photographic plates illu trate the chapter on "Food and Fancy Fishes," whic will be of considerable value to local naturalists. A fe new species are recorded.

The concluding chapter is entitled "Potentialities and summarises in an able manner the vast store of foo and wealth which is furnished by the Great Barrier Re and is still unappropriated.

There can be but little doubt if a serious fishery of t dugong is undertaken that interesting sirenian will soo become exterminated. It is not very evident why t "Great Barrier Reef sea-serpent" (*Chelosauria Lovell* n. gen. and sp.) should be placed among the potentialiti of the Great Reef. A detailed description and sketch are given of a supposed enormous Chelonian, with snak like head and fish-like tail. Dr. Günther, it appears, h offered "£100 for the entire animal, £50 for part, and fair price for the head and neck sun-dried." An exte sive fishery at these prices—for doubtless other curato would be willing to purchase—may perhaps be regarde as a possible, if improbable, source of wealth.

The author puts in a plea for a federal Australia marine biological station at Thursday Island in Torr Straits, which should "look for the main means of i foundation and maintenance to Australian corpora support and Australian private liberality." The Review would like to add his testimony to the suitability Thursday Island for this purpose. It is convenient fro every point of view, being easy of access, with a regul mail and a telegraph, a safe anchorage, extensive an prolific reefs almost entirely surrounding the island, an inexhaustible reefs in the vicinity. Mr. Saville-Kent's boo hows, as do also the series of papers by various experts, :hich are now being published by the Royal Dublin ociety, that the fauna is one of extreme interest. A iarine biological laboratory is one of those institutions ı which, beyond all question, the interests of pure :ience and its applications to industry and commerce re so interwoven that there need not be any hesitation ı endowing and supporting it by the most "practical" ıinded individual or Government.

There is evidence in the shape of numerous misprints that ıe author produced the book under stress of time. The ystematic zoologist has a right to complain of Mr. Saville-{ent's practice of naming imperfectly diagnosed genera nd species. In hardly a single case is there an adequate escription of a new species. Being himself a zoologist, e should have been more considerate to his colleagues.

It is difficult to criticise the sixteen coloured plates 'hich conclude the volume. They contain over two undred colour sketches, selected out of a much larger umber from the author's note books. This being so, e may regard them as colour memoranda, taken on the pot and grouped as plates. Very few of them can be garded as drawings of the animals, since, as a rule, ıe critical points of form are omitted. The reviewer as checked the colours of some of the animals depicted y sketches made by himself of the same species, and e finds that Mr. Saville-Kent's colouration, or rather ıe lithographer's rendering of it, is accurate enough, ut there is no doubt that the plates are very crude. nartistic as they are, they serve to emphasise the glorious auna of the coral seas.

ALFRED C. HADDON.

BACTERIOLOGY FOR THE PUBLIC.

l Manual of Bacteriology. By A. B. Griffiths, Ph.D., F.R.S.E., F.C.S. (Heinemann's Scientific Handbook Series). Small crown 8vo. Illustrated. (London: Heinemann, 1893.)

THE number of bacteriological text-books is still comparatively so small, that each successive endeavour › expound the principles of this new science attracts more eneral attention than is occasioned by the appearance of milar treatises in sciences which have already an abunance of such works in circulation. It might be supposed ıat because bacteriology is a science of such recent growth would be more easy to prepare a text-book of bacterilogy, than one dealing with a science the literature of 'hich extends over a much longer period of time. As a ıatter of fact, however, this is by no means the case, ›r probably in no other experimental science has so ıuch to be taken on trust, owing to the impossibility of epeating investigations under precisely similar conditions, s can be done in the case of physics and chemistry; 'hilst again from the very juvenility of the science of acteriology, there has not yet been sufficient time and pportunity for many of even the most important points › be firmly established through repeated observation by ifferent investigators. On this account there is the ıore scope for the exercise of the judgment and critical ıculty by the author of a work on bacteriology, and we re of opinion that a heavy load of responsibility rests pon the shoulders of a writer who undertakes to present › the public a worthy treatise on this important subject.

It is doubtless an appreciation of this grave responsibility which has deterred many well-qualified persons both in this country and on the Continent from publishing works dealing with more than comparatively small portions of this elastic and comprehensive science. The writer of the work before us plunges confidently into the task before him without even a moment's misgiving or hesitation; his preface does not contain a word which might betray any fear that the pages which are to follow may fail to do justice to "the important and far-reaching subject of bacteriology." The table of contents indicates that the information to be imparted in this little book of 348 small crown octavo pages, which are well printed in clear large type, is to be of a most comprehensive character. We find first, an introductory chapter, upon which follow the "bacteriological laboratory and its fittings," "methods of cultivating, staining, and mounting microbes," "origin, classification, and identification of microbes," "biology of microbes," "infectious diseases and microbes," "microbes of the air," "microbes of the soil," "microbes of water," "ptomaïnes and soluble ferments,' and lastly "germicides and antiseptics." To deal with this extensive material in such a small compass obviously requires that a very careful selection should be made of the matter which is to hand, in connection with each of the above divisions of the subject. The method of selection to be adopted in such a case must of course depend upon the kind of reader for which the book is intended, but this is a point on which we are not informed in the text nor on which have we been able to arrive at any conclusion from a perusal of the pages. The idea that the book is designed for the general reader is negatived by the fact that there occur long catalogues of bacterial species and of bacterial products, together with technical details which can only serve to increase the chaotic bewilderment in which the minds of most persons find themselves with regard to the subject of micro-organisms in general. On the other hand, for the serious student of bacteriology the information is as inadequate when detail is essential as it is discursive and wandering when terseness and precision are required. The entire work bears the impress of the hasty and premature compilation of undigested reading. We come to this conclusion, as it is almost impossible to believe that the author is so ignorant as some of his statements would indicate. Thus it would be uncharitable to believe that the author had written the following passage except by oversight: "Microbes may be simply divided into aërobic and anaërobic forms. *Bacillus spinosus* and *Bacillus œdematis maligni* are examples of the former; while *Micrococcus candicans* and *Bacillus subtilis* are examples of the latter kind." We feel sure that Dr. Griffiths is as well aware as the most elementary student of bacteriology that the *Bacillus subtilis* is a type of the aërobic and the *Bacillus œdematis maligni* a type of the anaërobic microbe. In the special description of *Bacillus subtilis* which follows in a later chapter we should be interested to learn on what authority this organism is described as "the hay-fever microbe." The same paragraph furnishes another excellent illustration of the kind of loose illogical writing in which this book abounds; thus, it is stated that "the action of ozone on both the spores and bacilli is that they are completely destroyed; this fact explains the absence of this and other microbes in the air at sea—the latter containing an appreciable amount of ozone." Innumerable experiments have surely proved that the absence of microbes in sea-air would be anticipated on mechanical grounds quite irrespectively of the possible subsidiary effect of ozone.

We believe that Dr. Griffiths is primarily a chemist, and a number of pages in this work are devoted to the chemical products elaborated by micro-organisms; in this connection we are informed that yeasts secrete a soluble enzyme which converts maltose into dextrose and levulose (*sic*), nor is it easy to believe that this is a *lapsus plumæ*, for the equation is given with the explanatory names beneath the formulæ, thus

$$\underset{\text{[maltose]}}{C_{12}H_{22}O_{11}} + H_2O = \underset{\text{[dextrose]}}{C_6H_{12}O_6} + \underset{\text{[levulose]}}{C_6H_{12}O_6}.$$

Dr. Griffiths devotes a number of pages to the subject of hydrophobia, but in connection with the hitherto undiscovered vital cause of this malady we hardly think that either the public or the scientific world will feel much interest in the author's statement that he has "observed a micrococcus in the saliva of a woman suffering from hydrophobia," notwithstanding the categorical assurance which follows that "this microbe does not occur in healthy human saliva."

In dealing with the much-vexed subject of the etiology of pneumonia, the author refers only to the pneumococcus of Friedländer which has long been regarded as an ineligible candidate for the distinction of being the specific cause of this disease, whilst of the far more probable diplococcus of Fränkel there is no mention whatever, nor indeed of the uncertainty which surrounds the entire question.

Similarly, in connection with the bacillus of typhoid fever we find no mention of the closely-allied *Bacillus coli communis*, nor does the author appear to be acquainted with any of the modern methods which have been resorted to for its diagnosis, but contents himself with copying a long passage from Gaffky's original paper of 1886 in which the statement is made that the well-known potato-test serves to distinguish this microbe from all others. Indeed, the transcription of long passages from the works of other authors is a striking feature in this book, and inasmuch as such extracts are not printed in different type, the reader must be ever on the alert for the small inverted comma, in order to know whether he has before him the words of Dr. Griffiths or those of some more or less distinguished authority.

We do not think that any useful purpose would be served in pursuing this criticism further, nor should we have referred to as many points as we have done but that we have such strong reason to believe that the circulation of works of this kind among some sections of the public is fraught with no little danger. It is by no means uncommon for persons without any special qualification whatever, but with plenty of cheap assurance and a smattering of information gleaned from semi-popular works like the one before us, to perambulate the country under the auspices of county councils and other equally competent bodies, and to deliver discourses or even write books on sanitary and hygienic subjects; so that if the sources from which these retailers of third-hand knowledge draw are g vously inaccurate, it requires but little imagination realise how serious may be the consequences.

THERMODYNAMICS.

Die Thermodynamik in der Chemie. Von J. J. v Laar. Mit einem Vorwort von Prof. Dr. J. H. van Hoff. Pp. xvi., and 196. (Amsterdam and Leip 1893.)

TWENTY years ago the first application of second law of thermodynamics to the study chemical phenomena was published by Horstmann, a shortly afterwards the whole subject was investigat by Willard Gibbs, but in a manner so general that work failed to gain the recognition of physical chemi for many years. Within the last decade, however, p gress in this direction has been very rapid, and spec branches or special aspects of chemical thermodynam have received exhaustive treatment at the hands van 't Hoff, Le Chatelier, Duhem, Planck, and othe But if we except the novel and brilliant exposition in t new edition of Ostwald's "Lehrbuch der allgemein Chemie," a general survey of the modern applicatio of thermodynamics to chemistry has hitherto been wan ing, and it is to supply this want that Dr. van Laar h written the present volume.

The first half of the book is concerned with gene thermodynamical principles and their application to t behaviour of gases and saturated vapours. The devi tions from the laws of perfect gases are considered ve fully—indeed, at inordinate length. As Prof. van 't H says in his preface, the work is alternately text-book a memoir. Now, while this method of treatment m have its advantages, it entails an utter absence of balan between the various parts of the work. It appears, f instance, out of all proportion to devote a fifteenth pa of the whole book to the discussion of the formula f the vapour pressure of a liquid. After making his wa through thirteen pages of infinite series, differenti equations, and determinants, the student finds tha when judiciously modified, van der Waals's equation ca be made to express exactly the relationship between th temperature and pressure of a vapour in contact with i liquid—a result (to the chemist, at least) quite incom mensurate with the trouble involved in arriving at it.

It is the second half of the work which is of speci interest to students of physical chemistry. Beginnin with the fundamental entropy principle of Gibbs, th author develops the various equilibrium equation and gives a general proof of the important relatio $d \log K/dT = Q/RT^2$. Then come applications to concre cases of dissociation and balanced action. The "tempe rature of transformation" of phases of constant com position and the "triple point" are next fully discusse and the last portion of the book is occupied with th behaviour of dilute solutions. Here the new theories o osmotic pressure and electrolytic dissociation are viewe from the thermodynamical standpoint, many importan constants being calculated afresh. The depression of th freezing point and of the vapour pressure in solutions, a well as the question of affinity constants, all receive ad quate treatment. In discussing neutralisation, however, the author has fallen into a serious error. On page 178 we find in italics the statement that "when a base and an acid are mixed in equivalent proportions in aqueous solution they are transformed entirely, no matter how weak they may be, into a salt and water." This is undoubtedly erroneous. A solution of potassium cyanide, for example, is never neutral, but always contains free potash and free prussic acid. The author has been led into this error by assuming in the construction of his equations that water is a perfect non-electrolyte, *i.e.* is not at all dissociated into ions.

The chief defects of the book are the want of proportion already alluded to, and the too bare formal mode of treatment. Fewer formulæ and more text would better suit the requirements of the average student. The typography and clear arrangement of the mathematical sections of the work are admirable. It is to be regretted, however, that the text has not had the advantage of revision by a German proof-reader. The Dutch compositor is presumably responsible for some quaint specimens of German, and oscillates in his spelling between antiquated forms like "dasz," "nähmlich," and painfully phonetic renderings such as "grafisch" and "Kwadratwurzel."

The book may be confidently recommended to those who already know the elements of thermodynamics and are desirous to learn the applications of that science to the problems of general chemistry.

J. W.

OUR BOOK SHELF.

Discussion of the Precision of Measurements. By Silas W. Holman. (London: Kegan Paul, Trench, Trübner, and Co., Ltd., 1892.)

THIS book deals with a subject that becomes more important every year, and its applications in nearly every science are both numerous and necessary. That our means of accurate measurement have reached a very fine stage, which is difficult to exceed, at any rate to a great extent, is well known, but results can be made of far greater value when subjected to a thorough discussion. In astronomy one may, perhaps, say that such discussions are carried through to their fullest extent and solving problems by the methods of least squares—a means of obtaining the most accurate values for the quantities sought after—is the rule and not the exception. To be able to find out the precision with which measurements have been made, whether by means of a yard-measure, the circle of a meridian instrument, or any other means, is at all times of great interest to the student of science, and the present work is intended especially as a course of study to engineers and for students of pure sciences, to present in a clear manner the principles on which such questions as, What accuracy is desired in the result? With what accuracy must each individual measure be obtained? and How trustworthy is the final result when obtained? &c., can be answered. The material here used is, as the author informs us, the outcome of several years' teaching of the subject, and a study of the volume itself indicates that he has presented it in a form that will commend itself to its readers. The book is divided mainly into three parts. The first deals with the treatment of direct measurements, the second with indirect, and the third with the determination of the best magnitudes of components. In the beginning the various sources of error, in different kinds of measurement, are pointed out, and the reader is made familiar with determinate and indeterminate errors, deviations, general laws of deviations, &c., terminating with two fully-worked out examples relating to the balance and voltmeter calibration. Part ii. gives in a clear way the methods of procedure with regard to indirect measurements, several examples being interpolated illustrative of the rules described. The third and last part is devoted to the solution of a certain class of problems, which deal more with the use of the instruments with which the observations are ma e, than with the observations themselves. Thus, for instance, in using a tangent galvanometer to find the best angle of the needle which will give the least errors of reading. This and several other problems, taking the cases when there are one, two, three, or more components, are thoroughly worked out. The book concludes with a series of illustrative examples.

Traité Pratique d'Analyse Chimique et de Recherches Toxicologiques. Par G. Guérin. (Paris: Georges Carré, 1893.)

THIS book differs in several important respects from ordinary works on analytical chemistry.

The first three parts are concerned with the ordinary processes of qualitative analysis—wet and dry reactions. the separation of group precipitates, &c. As special features of these sections it may be noted that coloured representations of borax beads and of beads of microcosmic salt are supplied, and that the reactions of the rare metals and of acids such as bromic, selenic, butyric, malic, meconic, &c., which are but seldom introduced into text-books, are fully discussed.

After a short section dealing with the qualitative analysis of gaseous substances, the author deals with spectroscopic methods of analysis. In this part are described the various forms of spectroscope, and the modes of obtaining and observing both emission and absorption spectra. A table is given of the characteristic rays in the emission spectra of the different elements arranged in order of their wave-lengths. In connection with absorption spectra, chlorophyll, salts of didymium and erbium, potassium permanganate, and blood, including the treatment of blood-stains, are considered. Both emission and absorption spectra are illustrated by means of coloured charts.

Part vi., which is by far the most extensive, is devoted to toxicology. The conduct of chemico-legal inquiries in cases of suspected poisoning by arsenic, phosphorus, hydrocyanic acid, chloroform, and chloral are first given in detail. Then are considered the general reactions and, where devised, the modes of separation of the vegetable alkaloids and the alkaloids of animal origin, the ptomaines and leucomaines. This section is completed by a full and historical account of the characteristic chemical properties and physiological action of the principal alkaloids.

Quantitative methods only find a place in the last part of the book, where the author introduces the examination of potable and mineral waters, and the estimation of clays, irons, and steels. In this part the apparatus and methods used in the bacteriological study of water are also included. An appendix relating to the preparation and concentration of reagents and a full index are supplied.

The prominence given to the reactions of the rare metals, the introduction of spectroscopic methods, and in particular the chapters on toxicology, make the work a valuable addition to the literature on analysis. It may be noted, however, that when dealing with the constitution of substances like the alkaloids, the author occasionally uses formulæ which are as yet far from being definitely established.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Identification.

PERMIT me to make in your columns a few remarks on the following topic:—

It is now well known that the Council of the British Association have lately memorialised the Secretaries of State for the Home Department, Army, Navy, India, and the Colonies, expressing an opinion that the Anthropometric methods for Identification in use in France and elsewhere, deserve serious inquiry, as to their efficiency, the cost of their maintenance, their general utility, and the propriety of introducing them, or any modification of them, into the Criminal Department of the Home Office, into the Recruiting Departments of the Army and Navy, or in the Indian and Colonial Administration.

In connection with this suggested inquiry I have some very recent information to give as regards the inclusion of finger prints among the records that admit of being usefully employed in *bertillonage.* This convenient term has been coined to express the principle of the French system, invented and directed by Alphonse Bertillon, of so classifying anthropometric records that each can be sorted into its own natural group, just as each surname falls into its alphabetical place in a common directory. There may be many Smiths, but every Smith will be found among the Smiths and not among the Browns. There may be doubt about the exact spelling, and the Smythes will have also to be searched, but the range of uncertainty as to where to look for the required name will always be narrowly limited. So it is with the ordinary anthropometric records; so also it is with finger prints, which are as yet unused in the French system. Those who have read my book on the subject will recollect that the index letters for finger prints are limited to *a*, *u*, *r*, or *w*, as the case may be, for the two forefingers, and *a*, *l*, *w*, for the remaining eight digits. These produce such combinations of ten letters as *ral*, *ull*; *wl*, *ll*, which are arranged alphabetically. The test of the efficiency of this system lies, *first* in the sureness with which different (instructed) persons assign the same index letters to the same indifferently printed set, and *secondly* in the degree to which the sets are differentiated by their classification. Now I possess and have examined some thousands of well printed sets of students and others at my laboratory; but until very recently I had no large collection of *ill*-printed sets of *prisoners.* This want has been at length supplied in the following manner, by which I am able to confirm previous conclusions. Lieut.-Col. Surgeon Hendley, whose energetic furtherance of science and art at Jeypore is well known, was in charge last year of the Maharajah's magnificent contribution to the Imperial Institute, and, having visited my laboratory, became much interested in finger prints, and promised to send me a collection taken from the gaols of Jeypore. It arrived not very many days ago, too late to be alluded to in my recently issued supplementary chapter on the Decipherment of Blurred Finger Prints. It contains nearly a thousand cards, each card bearing the impressions of all the ten digits of a different person. They were printed by pressing the finger first on the pad used for inking the office stamp and then on the card. This method, as I have recently had occasion to point out, gives far inferior results to that of printers' ink. So far as the Jeypore collection shows favourable results, a similar collection printed in the way always used in my laboratory would give still better ones.

Consequently, the Jeypore collection is particularly serviceable for arriving at moderate conclusions; moreover, their number is sufficiently large to justify them. My assistant marked the appropriate index letters on each card, and I compared them with my own independent determinations. The result was very favourable; our readings practically agreed, and although most of the prints were faint, or blurred, or otherwise imperfect, it was possible to classify nearly all of them. This affords a strong confirmation to my formerly expressed belief that the method of finger prints must, in time, come into use as an important and supplementary aid to *bertillonage.* The process of taking the impressions is extremely simple after it has been learnt and the small but necessary equipment is at hand. At the same time, there is no undressing necessary, and nothing else of a humiliating charac to be undergone during the brief act of making the prints.

I shall not here enter upon the unique and extraordina power of finger prints in enabling us to determine, irrespective of age and growth, whether two clear impressions, taken at d ferent dates, were or were not made by the same finger. does not depend on that general pattern of the print which the basis of classification, but upon the numerous forks a other details in the ridges that compose the patterns. T has been fully discussed and proved in my two books, and I ha nothing new to say, except that in my laboratory I have n upwards of 300 complete duplicate sets to work upon, the t members of each of which were taken at times separat by various intervals ranging between one and three yea These intervals are too short to be of much value, but the c lection will increase in importance as the years go by, a further repetitions of prints from the same fingers shall ha been made.

My letter is already long, so perhaps you will permit me another occasion to recur to the action of the Council of t British Association, and to indicate the character of the inform tion regarding the efficiency, cost, and utility of *bertillona* that might be gained with little trouble officially, but which almost beyond the reach of any private person to obtain.

FRANCIS GALTON.

The Publication of Physical Papers.

MR. SWINBURNE in his letter on this subject has omitt to recognise the existence of a society which is older and qui as important as the Physical Society, I mean the "Lond Mathematical Society."

For reasons which it is unnecessary to enter into, I fear th an impression has unfortunately got abroad that the Lond Mathematical Society is an institution which exists solely f the advancement of *pure* mathematics. No greater error cou be made; for whatever may have been the case in the earli days of the society, the council for some years past have be fully alive to the importance of doing everything they can encourage mathematical physics, and to induce physicist whether members of the society or not, to communicate pape on mathematical physics. In short, the policy of the counc at the present time is to endeavour to hold the balance even between the two branches of mathematics, and not to favo the one more than the other.

The policy of the society is still further exemplified by th fact that on the last two occasions the De Morgan medal h been awarded alternately to a mathematical physicist and to pure mathematician; and during the discussion which too place in connection with the last award to Prof. Klein, sever members of the council expressed a hope that this practic would be followed in future years.

A scientific newspaper like NATURE is scarcely suitable for th publication *in extenso* of papers relating to mathematic physics; but it may be well to point out that the Londo Mathematical Society presents contributors of papers wi twenty-five *gratuitous* copies, whereas the proprietors of th *Philosophical Magazine* refuse to present gratuitous copies or remunerate contributors in any way whatever. Moreover, th Proceedings of the Society can be purchased by the publi whilst (according to Mr. Swinburne) those of the Physica Society cannot. Also abstracts of papers read at the meeting of the London Mathematical Society can always, if the auth wishes it, be published in NATURE, and can thus be at onc brought before the notice of the scientific public.

It will thus be seen that the London Mathematical Societ offers greater advantages to contributors than the Physica Society or the *Philosophical Magazine;* and when this fact i once recognised I venture to hope that physicists will not stan aloof from the Society in the way that many of them hav hitherto done.

A. B. BASSET.

A Simple Rule for finding the Day of the Week corre sponding to any given Day of the Month and Year.

MR. H. W. W., in NATURE, vol. xlvii. p. 509, gives simple rule for finding the day of the week corresponding t any given date. It seems that this rule could be made stil more simple. Thus, let

A = number of the given year.
B = number of the day in the year.
C = number of leap years from A.D. 1 to the beginning o

the given year—viz. $(A-1) \div 4$, neglecting the remainder. Add these numbers together, and from the total subtract D = the number of secular years, which were ordinary years (100, 200, 300, 500, &c.). The sum is then divided by 7, and the remainder is the day of the week.

Example: June 18, 1815. $1815 + 169 + 453 - 14 = 2423 \div 7$. The remainder = 1. Therefore the day is Sunday.

This method holds good for any century according to the Gregorian Calendar. For the Julian reckoning, the rule is the same, only we must omit the number D, and write -2 in its place. The rule is then good without any change for any century.

Example: Oct. 14, 1066. $1066 + 287 + 266 - 2 = 1617 \div 7$. The remainder = 0 = 7th day, Saturday. C. BRAUN.

Mariaschein, Bohemia, June 15.

The Fundamental Axioms of Dynamics.

PROF. LODGE (NATURE, p. 174) maintains, in opposition to my correction, that your report of his recent paper on dynamical axioms was accurate in making the following statement:—"Dr. MacGregor objects to the author's definition of energy as the name given to 'work done,' and contends that this definition assumes conservation." He cites in proof the first two pages of my paper in the February number of the *Phil. Mag.* These pages, however, contain no reference to this definition, but a discussion of his definition of energy as *the effect of work done*. The definition of energy as a name given to work done is discussed on the fourth page, where the following will be found:—"In a second version of the above argument Newton's third law and contact action *are the only assumptions made . . .* The definition of energy in this argument is quite different from that of the earlier paper:—'Energy is that which a body loses when it does work; and it is to be measured as numerically equal to the work done.' There is here no reference to working-power. Loss of energy is simply a synonym for work done by, and gain of energy for work done on."

J. G. MACGREGOR.

Royal Society, Edinburgh, June 23.

Artistic Rows of Elms.

IN your Notes, p. 182, June 22, you say that "a correspondent desires to know where to find any celebrated and artistic hedgerows of elms within about thirty or forty miles of London."

If he will travel down to Sittingbourne, which is about forty-five miles by rail, and five miles less by road, from London, he can see some fine elms on the south and west bounds of the Murston Rectory Pastures, locally known as the Park.

The southern toll of elms is a triple row about 130 paces in length, the western toll of elms is on Gaze Hill, and is a double row about 212 paces in length. These elms must have been planted before this century. Being on elevated land they are well seen from considerable distances in the neighbourhood. Singularly enough they do not belong to the glebe. The southern toll, however, belongs to the patrons of the living, and the western toll to my predecessor, the Rev. J. S. Hoare, who purchased them, with the land they stand on, from the late Mr. Twopenny, of Woodstock, Tunstall. I have not yet been able to persuade the patrons of the living to purchase them from the present owner. ALEX. FREEMAN.

Murston Rectory, Sittingbourne, June 27.

Soaring of Hawk.

THE rest-house in which I now am stands close to the edge of a precipitous descent. There is a covered verandah in front, and we are nearly 9000 feet above the sea. I have just seen a hawk, or vulture hawk, circle round three times over the precipice. The whole time its wings were motionless (to the sight). Its first circle was on a level with me, the second was higher, the third was unquestionably higher still. As I sat I could see both the complete first and second circles. To see the last I should have had to go to the edge of the verandah. This appears to be a clear case of rising circles without (apparent) motion of the wings. I have seen the same thing from the plains, but have not been so sure of the fact observed. There is a light wind blowing, scarcely moving the trees.

The part of the circle near me was, in the first and second cases, within a few feet of where I sat, the third was *over* the roof of the verandah, and out of my line of sight.

Changla Gali, May 25. F. C. CONSTABLE.

Carrier Pigeons.

PROF. MAREY states in his "Animal Mechanism," p. 214, "that a bird which has traversed in a single flight a distance of fifty leagues (which it seems to do without taking any food) weighs only a few grammes less than at its departure." I shall be grateful to any of your readers who will inform me where evidence of this is to be found. The enormous amount of food consumed by birds would seem to show that the processes of loss and repair go on in their bodies with great rapidity.

F. W. HEADLEY.

Haileybury College, Hertford, June 27.

A Method of obtaining Glochidia.

THE Glochidia of Anodon are not always easy to obtain. They appear to be retained, and shed only when fish are swimming near.

Tadpoles have the same influence as fish, and a good supply of Glochida may be obtained by examining the tails of tadpoles swimming in a dish in which a few Anodons have been placed.

G. P. DARNELL-SMITH.

60, St. Michael's Hill, Bristol, June 26.

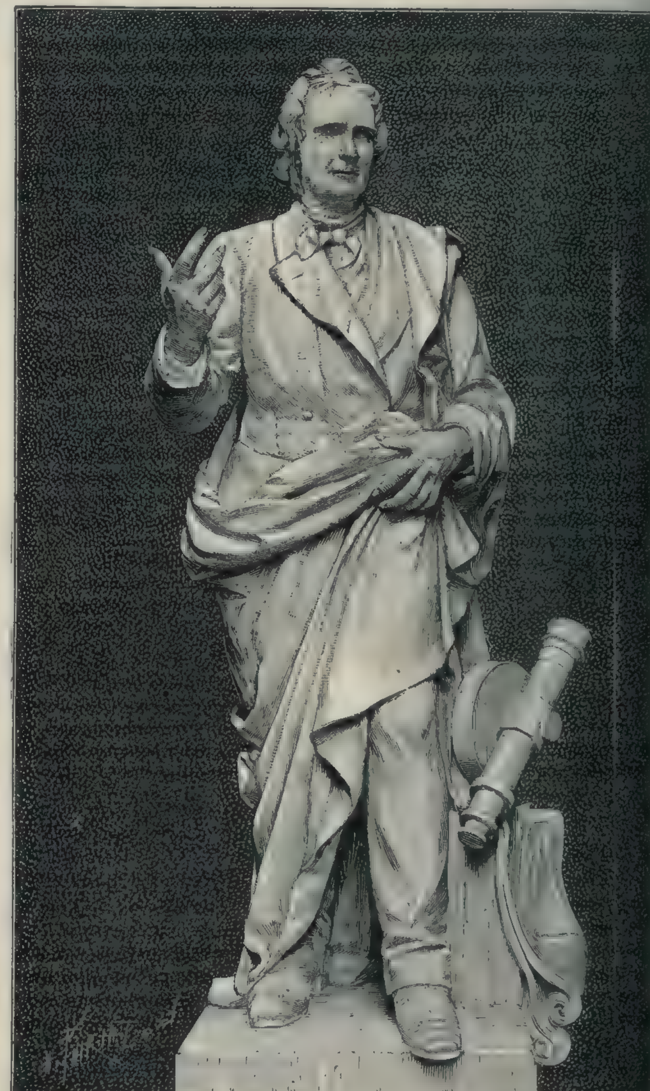
A NEW STATUE OF ARAGO.

IN this country the prevailing opinion is that the works of a man of science furnish the best monument to his memory. Though something can be said in favour of that principle, the restriction of its application to students and interpreters of nature is by no means justifiable. But a "look around" at the statues, and tablets, and other marks of public appreciation, shows that a man's greatness is, in general, not measured by his scientific labours. They do these things better in France. Those who honour a man and his works desire to proclaim his fame in the market-place, so that all may know that he was a giant among men. Passers-by are thus brought to a knowledge of deeds that they wot not of, and they see that a life devoted to science is one to be emulated. Thoughts of this kind forced themselves upon us when it was announced a few weeks ago that a statue to Arago had been unveiled in Paris.

Fourteen years ago a statue to Arago was erected at Perpignan, near his birthplace, and in 1886 it was decided to commemorate the centenary of his birth by raising the funds for erecting a statue at Paris. A committee, having the late Admiral Mouchez for its president, was then formed, and an appeal for subscriptions was made. Thanks to the contributions from the State and the Municipal Council of Paris, the necessary money was soon raised, and M. Oliva was commissioned as the sculptor. The statue has been completed for some time, and it would have been unveiled last summer but for the death of the artist, and later, of Admiral Mouchez, who was the prime mover in the matter.

The inauguration of the statue at the back of the Paris Observatory took place under M. Poincaré, Minister of Public Instruction, on June 11. Among those present were M. E. Arago, French Ambassador at Berne, and son of the renowned astronomer; M. Tisserand, the director of the Paris Observatory; M. Cornu, M. Huet, representing the Prefect of the Seine; and M. Muzet, vice-president of the Municipal Council of Paris. Each of these gentlemen dwelt in eulogistic terms on the career of Arago as a public man as well as a man of science. "Arago introduced physics into astronomy," said M. Tisserand, "and gave it a permanent place. Before him, astronomers concerned themselves chiefly with the movements of stars and members of our planetary system, seeking to explain them in their minutest details by the law of gravitation. Arago studied the nature of heavenly bodies, and the character of the phenomena continually exhibited by them. The polariscope showed him that the glaring surface of the sun is gaseous, and gave him important information as to the light of comets. Another application of physical methods furnished him with a precise means for measuring the diameters of planets or determining their magnitude. Nothing is more ingenious than his explanation of the scintillation of stars, founded upon the remarkable properties Fresnel found to be possessed by rays of light. Arago ought truly to be considered as the founder of a branch of astronomy—physical astronomy—that has since been remarkably extended, for it was he who pointed out the importance that would accrue from the application of photography to the study of celestial bodies. He was not able to foresee the day, however, when chemistry would enter into the domain of astronomy, and we should be able to discover their constitution; spectrum analysis has only been discovered, in fact, since the death of Arago."

"An example will give an idea of the perspicacity of Arago. It is generally known that about the end of last century France took the initiative of the metrical system and made it an international thing by connecting the metre with the size of the earth. But our globe is cooling and contracts, little by little, in the course of centuries, so that the unit of length is rendered liable to slight changes. Arago thought that a minute study of the light-rays that come to us from the sun and stars might furnish a rigorously constant unit of length, connected not with the earth, but with the stars—a sidereal metre of some kind. Well, this beautiful idea was realised a few months ago by Mr. Michelson, at the American Bureau of Weights and Measures." M. Tisserand also dwelt upon the influence that Arago exercised upon his pupils and the comprehensive character of his literary works. M. Cornu followed with an account of Arago's investigations in experimental physics, and after stating his work in connection with the *experimentum crucis* of the emission and wave theories of light, said, "If we come to terrestrial physics, meteorology, or industrial applications of steam and electricity, we always find Arago in the front rank with new ideas. Of an indefatigable activity, in science as in government, he was present with all the resources of his powerful spirit, with the ardour of his generous heart, especially where there was a great work to direct, a just cause to defend, a social evil to fight, and, at the call of duty, a peril to face."



The character of the statue, which is in bronze, is shown in the accompanying illustration from *La Nature.* Arago has his face turned towards the observatory. The pedestal on which the figure stands is also in bronze, and bears the simple inscription "FRANÇOIS ARAGO, 1786–1853. SOUSCRIPTION NATIONALE." Men of science throughout the world respect the name, and their French *confrères* revere it. Those who have done homage to the man by thus assisting to perpetuate his memory are themselves honoured in the act.

MODERN MYCOLOGY.[1]

It is not often that a great and industrious investigator lives to see his chief work so far completed as Prof. Brefeld has done; and still more rarely to find an enthusiastic exponent of all his views so willing and so capable of putting them before the public as Dr. von Tavel here proves himself to be.

It is hardly thirty years ago since the late Prof. de Bary of Strasburg showed that the study of the fungi, up to that time a chaos of statements in which the student usually lost himself hopelessly, was capable of being made not only a very scientific and important branch of Botany, but also a very interesting one, and that there were already workers in the field—especially the Tulasnes—who were showing how to do this, by patient and thorough investigations of each species that could be properly studied.

De Bary himself founded a school of exact inquirers,

[1] "Vergleichende Morphologie der Pilze." By Dr. F. Von Tavel (Jena: Fischer, 1892.)

whose brilliant discoveries on the nature of parasitism and the development of the fungi, and above all, the propounding and testing of intelligent theories to explain the facts observed, will never be forgotten.

Brefeld was driven, at an early period of his investigations, to differ entirely from De Bary regarding a fundamental point in the morphology of the fungi. Certain organs discovered by De Bary in the simpler ascomycetes were regarded by him as morphologically sexual organs, and in later years the doctrine of the sexuality of the fungi became a central pivot around which the whole question of the morphology and evolution of these remarkable cryptogams turned.

As is well known, De Bary showed that if his interpretation of the facts was right, we have the principal groups of the fungi ascending along one main path of development. Starting with the *Phycomycetes*, which include the mucors and the fungi of the potato-disease and vine-disease (and which are so obviously allied to certain green algæ that it was impossible to doubt that these lower fungi are derived from green algæ), the main path of evolution was traced through the lower ascomycetes, such as the fungi of the hop-disease, and the higher members of the same series—*e.g.* ergot of rye, the larch-disease, &c., and found to end in the Uredineæ or "rusts," and basidiomycetes—the mushrooms, toadstools, and puff-balls, &c.

From this main series, branches were regarded as given out at various points, as the *Chytridiaceæ*, *Ustilagineæ*—the "smuts" and "bunts" of our cereals, &c.—and so on.

De Bary pointed out very clearly that the most astonishing morphological phenomenon observable in the fungi is the gradual loss of first functional sexuality, and then of even the last traces of sexual organs, as we ascend from the lower to the higher fungi.

Brefeld—and it should be stated that the book before us is almost entirely an admirable short edition of Brefeld's ten large volumes—maintains that De Bary and his pupils were wrong in interpreting the organs of the ascomycetes in question as sexual, and that the loss of sexuality among fungi occurs much sooner than was supposed. The sexual organs, in fact, disappear within the limits of the *Phycomycetes* themselves, and De Bary's ascocarp and pollinodium lose all the significance his hypothesis assigned to them.

But De Bary's chief mistake—into which he was led by the above interpretation of his own observations—was in deriving his ascomycetous series from *the wrong branch of the Phycomycetes*. Instead of their origin being from the Peronosporeæ (*Oomycetes*) the ascomycetes are derived from the *Zygomycetes*, their line of descent passing through a group containing *Protomyces* and *Thelebolus*, and which group Brefeld terms the Hemiasci.

The oomycetes, indeed, are regarded as leading nowhere, except to the richly branched genera which compose it.

While the ascomycetes represent an enormously branched and successful series of forms which have specialized the type of the *sporangium* more and more, the basidiomycetes (in which the author includes uredineæ) have come off from another group of zygomycetes, and have specialized the *conidium* as their type of reproductive organ. The half-way group along this line is the Ustilagineæ, and Brefeld terms them Hemibasidii, accordingly.

The grounds for these revolutionary views cannot of course be explained in a review. They depend upon the numerous new facts brought to light by the untiring devotion and industry displayed in the Münster laboratory, and which are very clearly described and illustrated in the book before us.

A number of new forms have been discovered, of which the simple *Ascoidea rubescens* is an interesting example. Very instructive types, as yet unknown in text-books, are *Thelebolus*, *Pilacre*, *Tomentella*, *Tylostoma*, and some others; owing partly to the new facts brought out regarding them, and partly to the suggestiveness of the new views as to their morphology, such forms bid fair to become as well known in future hand-books as *Mucor*, *Podosphæra*, and *Agaricus*, are in those of to-day.

The generalizations regarding the comparative morphology of the reproductive organs of fungi as a whole are distinctly an advance, and show a delightful gleam of light leading to freedom from the chaos of terms the subject has laboured under: "pycnidia" and "spermogonia" disappear as such—they are merely chambers in which conidia are developed (*conidien-früchte*), the germination of numerous spermatia by Brefeld and others having established the conidial character of those mysterious particles, the spermatia.

The author's views regarding *Chlamydospores* will probably cause surprise to many who have not followed the progress of Brefeld's work during the last few years. If these views are accepted, the principal "spores" of *Protomyces*, the *Ustilagineæ*, and the *Uredineæ* are all to be interpreted as *Chlamydospores*, homologous with the resting spores of Mücor; even more startling is the discovery of such Chlamydospores (including "oidia" and "gemmæ") among the higher ascomycetes and basidiomycetes, novelties which are only equalled perhaps by the rich series of true conidial spores found in the latter group.

Zopf's work on fungi had already prepared us, in 1890, for some of the changes which these discoveries entail, but Zopf was not prepared for anything like the revolution which Von Tavel has accepted—and, indeed, so great a change of front was impossible before the publication of Brefeld's ninth and tenth volumes.

The new "comparative morphology of the fungi" certainly offers many advantages in the simplification of our views as to the nature of the spore, and promises to remove the bone of contention which this item has always offered to mycologists. We are asked now to accept the following view. There are four types of sporogenous organs in fungi:—(1) The *sexual spore*, only met with in the lower fungi (*Phycomycetes*), as the zygospore and the oospore, and gradually losing the sexual character within the group. (2) The *endospore*, formed asexually in a sporangium, and occurring as zoospores (Peronosporeæ, &c.), sporangiospores (*Mucor*, *Thelebolus*, &c.), or ascospores (all ascomycetes), the ascus being merely a sporangium of *definite* shape and size, and containing a *definite* number of endospores. (3) The *conidium*, which starts as a one-spored sporangium where *the sporangial wall and that of the contained spore fuse*, illustrated by the "yeasts" of Ustilagineæ and many ascomycetes, the "sporida" of Uredineæ, and the "conidia," "stylospores," "spermatia," &c., of Uredineæ and ascomycetes. The "*Basidium*" is merely a specialised conidiophore where *the position and number of the conidia* ("basidiospores") *are constant*, and true conidia occur in the group in addition—*e.g. Heterobasidion*, *Tomentella*, &c. Indeed, it is the play on this type leading to gradual specialisation which characterises the whole Basidiomycetous series. (4) The *Chlamydospore*, which, in the form of the type or of so-called "oidia," "gemmæ" occurs generally in all the series, and becomes specialised into "fructifications" in the *Uredineæ*.

This is perhaps a fair sketch of the central ideas of the new school, though it by no means summarizes or even mentions dozens of other interesting points brought out in the book under review, such as the remarkable evolutions of the germination—*e.g.* in *Nectria*—of the conidiophore—*e.g.* in *Peziza*—of the conidium, the basidium, the ascus, &c.

In conclusion, it may be pointed out that although Von

Tavel writes more fairly with regard to the work done by other schools, and has wisely avoided the bitter methods adopted by Brefeld towards De Bary's pupils in some of his volumes, there still seems to persist a tone of under-valuation of the work of the Strasburg school. After all, it should never be forgotten that unless De Bary and his pupils had followed up the clue—however false it may prove—of the "sexuality" of the ascomycetes, the matter would have had to be investigated, and the fact that the Münster school is enabled to explain the phenomena seen in a new sense proves how valuable De Bary's careful observations were. Moreover, however probable Brefeld's view of the origin of the ascomycetous series is—and it is now the clearest story yet put forward—many of his own facts show that the *impossibility* of De Bary's view of a sexual origin, now lost, of the ascocarp, is by no means proved. Brefeld insists that the simplest ascocarp (*e.g. Thelebolus*) may be derived by suppressing the stalk and withdrawing the sporangium of a form like *Mortierella* into the investing barren hyphæ at its base; but the *zygote* of *Mortierella* also has investing hyphæ, and it would not be going much further to suppose the sporangium of the germinated zygospore of such a form to be similarly withdrawn into the invested capsule. This "wild hypothesis" would not alter Brefeld's view as to the homology of the ascus, or the derivation of the ascomycetes from the zygomycetes, but it would, and very materially, alter the attitude adopted towards the sexual hypothesis. We have termed the suggestion "wild," but it is possibly not more so than Brefeld's own hypothesis as to the nature and evolution of the chlamydospore, and we imagine that the last word has not yet been said on either matter. However that may be, Brefeld's laurels of results are such as are won by very few investigators and Von Tavel is to be congratulated not only for his own discoveries, but also on his book, which is by far the best exposition of the subject in existence.

H. MARSHALL WARD.

DAUBRÉE ON THE GEOLOGICAL WORK OF HIGH-PRESSURE GAS.

A SERIES of experimental researches which promise to lead to important results, and which have already been applied by their author to the explanation of some difficult geological problems, have during the last few years been carried on by M. Daubrée. These experiments are concerned with the action of rapidly moving and high-pressure gas on rock masses, and lead to the conclusion that such high-pressure gas is a geological agent of no small importance. To carry out such experiments is no easy matter, but M. Daubrée has been fortunate enough to obtain the use of the apparatus used in the testing of explosives in the *Laboratoire Centrale des Poudres et Saltpêtres.* The high-pressure gas has been obtained by the explosion of gun-cotton and dynamite, the explosions being made in a steel cylinder with very thick walls, and closed at both ends with steel plugs. One of these plugs is fitted with a platinum wire, by the heating of which the charge can be exploded. The other, which under ordinary circumstances contains the manometer for measuring the force of an explosion, is modified so as to contain a block of the rock to be experimented on. A circular hole, moreover, is made at one end so that the gas, after traversing the rock, is allowed to escape. The rock, cut in the form of a cylinder, is supported between a steel stopper and the head of a piston. The charge of gun-cotton or dynamite usually filled a tenth part of the interior, and the pressures obtained were from 1100 to 1700 atmospheres. In one experiment the pressure was increased to 2300, and in another the still greater pressure of 2400 atmospheres was obtained. Many different kinds of rock were used, such as limestone, gypsum, slate, and granite, and each cylindrical block experimented on was cut through by a diametrical plane. In some of the experiments an additional very fine perforation was made along this plane.

As a result of the sudden shock of the explosions most of the rocks were fractured. In the case of the slate this resulted in faulting. The limestone and granite were broken up and crushed, but under the influence of the pressure the small fragments were quickly consolidated so as to resemble the original rock. This property of reconsolidating under pressure, thus shown to be possessed by rocks, seems analogous to the plasticity of ice observed by Tyndall.

All the rocks experimented upon, even the most tenacious, have undergone more or less erosion. The gases have disintegrated and pulverised them, and carried out the fragments. When their action was concentrated along certain lines, true perforations—that is to say, rounded channels more or less regular—were eroded through the blocks. In the case of a granite block the original perforation of 1·2 mm. was increased to a channel of 11 mm. The walls of these perforations after the explosions were found to be striated and polished. Sometimes the striations are parallel, like those produced by ice. At other times they spread in fan-form, and sometimes they are slightly curved.

The products of erosion are thrown out into the atmosphere, and an examination of the powder thus produced shows that a portion of the same possesses an interesting resemblance to the dust usually held to be of cosmic origin.

M. Daubrée applies the results of his experiments to explain the remarkable "diamond pipes" of South Africa. These diamond deposits are described by M. Mouelle in the *Annales des Mines* (tome vii. p. 193, 1885) as filling in cylindrical cavities of unknown depths in the rocks. These cavities appear to be cut out of the subjacent sedimentary or eruptive rocks, their upper parts are filled with a soft yellow decomposed rock matter, while below they contain hard volcanic conglomerate. They vary in size from a diameter of 30 to one of 450 m., and are originally surmounted by slight eminences, known as *kopyes* (little heads).

An interesting point about the general arrangement of the "pipes" is their occurrence along a straight line of 200 kilometres in length. Their walls, again, are smoothed and finely striated. These striations are often parallel, and indicate a powerful thrust from below upwards. No alteration is observable in the beds of shale forming the walls, except a slight elevation of their edges.

Thus in their general form, as long, narrow, cylindrical perforations in the earth's crust, they resemble the artificially produced perforations in the rocks experimented on. Their arrangement along a straight line suggests that they may have been opened along a line of fracture as were the perforations in the experiments. In the latter, the line of the eroded channel was determined by a very narrow perforation, and M. Daubrée suggests that in the former the positions of the "pipes" may have been determined in some cases by cross-fractures. The polishing and striation of the walls of the diamond pipes, again, is reproduced in the polishing and striation of the perforations in the experiments.

Another application of his experimental results made by M. Daubrée is to explain the opening out of the channels by which volcanic products reach the surface. Here, again, the linear arrangement of volcanoes, which has been so frequently pointed out, is noted as connecting volcanic vents with the experimental results. These are supposed to lie along lines of fracture, and each volcano is supposed to have been determined by a cross fracture, or some other cause, facilitating the passage of gas at that particular point. That there are reservoirs of gaseous pressure of great power below the surface is evident from volcanic phenomena generally, and given a line of fracture, with cross fractures, or other predisposing causes, the experiments prove that high pressure gas is capable of opening out cylindrical passages by which molten rock matter and fragments may reach the surface. In this connection, M. Daubrée points out the occurrence of volcanic craters, of which the cones are formed entirely of rock fragments, and known as "craters of explosion." Thus, near Confolens, in Velay, there is a crater excavated in the granite, and of which the cone is formed entirely of granitic fragments.

M. Daubrée further applies his experiments to explain, (1) the fracturing and crushing of rocks; (2) the transport of their debris; and (3) their apparent plasticity.

Some further results show that the high pressures of some of the earlier experiments are not essential, but that complete perforations can be obtained with pressures of 1100 atmospheres. A cylinder of granite, cut in two by a diametrical plane, and bound together with a ligature of copper, was thus excavated along its whole length by an irregular channel which opened on the surface by two branches. In the case of a cylinder of rock of which the height greatly exceeded the diameter the perforation tended to the form of two cones united by their summits. The action of the gases is not confined to the drilling of the perforations, they have likewise grooved and striated the surfaces of the divisional planes of the cylinders. These striations and groovings are not produced, as might be supposed, and as M. Daubrée himself at first believed, by solid particles of rock carried by the gas, and use as graving tools. It appears, in fact, that the gases themselves are able to striate and groove the rock on their first contact with it.

As an interesting corollary to his experiments, M. Daubrée points out, that leakage from steam pipes may in a similar way cut through metal plates. An example is quoted in which metal exposed to the escaping vapour from a steam pipe (pressure, seven atmospheres) was channelled and striated: the resulting marks were similar to those of a saw or file. A valve on a steam pipe, again, has been attacked in a similar way.

All these groovings in the metal have received a similar polish to that given by emery.

In the experiments the gases have in general caused the fusion of the surfaces which they have attacked. Thus, on the surfaces of the divisional plane of a granite cylinder the felspar is melted into white globules forming small projections. The plates of mica have also been softened. Even the quartz has not escaped, but appears pitted in a manner which recalls the erosion produced by hydrofluoric acid.

Scales of the rock are detached by the very unequal expansion as by a sort of shock.

A black crust exactly similar to the crust of meteorites has been produced with certain stones.

The transport of the debris produced in the perforation of the cylinders of rock is applied by M. Daubrée to the history of certain cosmic dusts, and the sediments existing in some of the deeper parts of the ocean. In making the perforations the gases carry out a quantity of debris. A part of this was collected on sheets of cardboard covered with vaseline. The particles arrange themselves in concentric circles on the sheet according to their size. Some of the large particles pierce the cardboard, and even its supporting plate; the very fine particles are carried to a distance by the gases, which they render opaque. In the powder retained on the cardboard, two sorts of grains can be distinguished under the microscope. The first are indistinguishable from those produced by simple mechanical pulverisation; the second have a special character intimately connected with the particular conditions of the experiment.

Thus, in the case of granite, fragments of all three constituents, quartz, felspar, and mica, are found in the powder produced. But besides this, minute, perfect or nearly perfect, spheres are found. These are opaque and black, or slightly translucent and brownish, with a glistening surface, and sometimes furnished with a very characteristic neck. They are doubtless the products of fusion.

This latter part of the powder of erosion seems identical with certain parts of the atmospheric dust, and that found in the deeper ocean, as well as in geological formations of various ages, and which have generally been looked upon as of extra-terrestrial origin. Thus the conclusion is arrived at that, while part of the so-called cosmic dust is undoubtedly of extra-terrestrial origin, the opening of volcanic and other channels in the earth's crust by high-pressure gas has also played an important part in its production.

Eruptive breccias may also have been produced by the force of high-pressure gas, as shown by the fracturing, breaking up, and reconsolidating of the rocks experimented upon.

A more remarkable fact is the passing back of the pounded and broken-up rock to its original solid state under the influence of the same gaseous pressure. Thus the fragments of the rock in the experiments were found to have moulded themselves so exactly on the containing steel apparatus as to have acquired a specular polish. The rock had, moreover, taken the impress of striations upon the steel. Limestone thus regenerated showed a schistosity concentric with the cylinder. It seems obvious, then, that the rocks of the earth's crust, having so frequently been subjected to enormous pressure, and so often folded and contorted, must in a similar way have been broken up and regenerated.

Another experiment showing the apparent plasticity of rocks is as follows:—

A cylinder of Carrara marble without a preliminary fissure, but with furrows on one of the ends and on the side, was placed in the apparatus and subjected to a pressure of 2400 atmospheres. It was afterwards found to be perforated with a channel, and moreover to be accurately moulded on the containing apparatus so as to take the impress of the concentric striations as in former experiments. The furrows were completely effaced, while the diameter of the cylinder was increased and its height diminished.

The ejection of rocky matter through the channels perforated by high-pressure gas occupies another paper. In such high-pressure gas M. Daubrée contends we have an agent capable of accounting for the facts in conformity with his experimental results. Special reference is made to certain trachytic domes—as, for example, those of the high plateau of Quito—of which the form seems to indicate that the rock matter forming them was ejected in an almost solid state. These domes, M. Daubrée supposes, crown the summits of orifices (diatremes) opened by the passage of high-pressure gas, and were themselves afterwards forced out by the same pressure. Attention is called to the remarkable uniformity in height observable in groups of volcanoes. This is explained as the result of origin from one common reservoir of pressure. The height of the volcanic cone gives a measure of this pressure. On the other hand, the hypothesis likewise explains the difference in height in different regions. Thus, in certain cases, reduction of pressure would be effected by lateral escape of gas, as happened in certain experiments in spite of the utmost care. A similar reduction of pressure may have occurred through the blocking of the channels of egress of the gas. This, too, occurred in certain of the experiments, notably when gypsum was the rock experimented on. With this rock the channel opened by the gas was quickly closed again by the rapidity with which the triturated rock resolidified. The paper concludes with a suggested application of the hypothesis to the cones and craters of the moon.

In another paper M. Daubrée returns to the subject of the flow of rocks under high pressure. With respect to this point he remarks that, in certain previous experiments, the rock not only accurately moulded itself to the apparatus, but also formed thimble-shaped protuberances outside it. Further experiments were conducted with round plates placed one upon another, instead of the former cylinders. Lead plates were first experimented on, and then these along with plates of rock. One of the most interesting results obtained was the production of little "eruptive cones" of lead or rock outside the apparatus. In one case the protuberance reached the height of 36 mm. After the experiments, some of the plates were found outside the apparatus in the form of circular capsules, so closely fitted into one another as to appear soldered. Some of the lead plates remaining in the apparatus were cut through in their central parts as with a punch. The thickness of these perforated plates was found to be diminished on their borders, and increased in their central portions. This effect may be compared to what occurs in many cases with contorted rocks. At the same time spaces were here and there formed between the plates thus united. Daubrée draws attention to the analogy between these spaces and those occurring between separate strata among contorted rocks, and which are often filled with metallic substances. Lamination was also produced in the plates of rock.

As a general designation for the accumulations of rocky matter crowning the summits of all perforations in the earth's crust opened by gaseous pressure, whether trachytic domes, lava flows, scoriæ cones, or the kopyes of South Africa, M Daubrée proposes the term "ecphysema" (French, *ecphysème*," Gr., ἐκφυσημα).

To sum up M. Daubrée's results:—

(1) High pressure gases from below are able to open out channels in the earth's crust, by means of which the same pressure can bring to the surface various products.

(2) In forming such channels the gases may striate and polish the walls of the perforations in a manner recalling that of glacial action.

(3) The products of such erosions are partly of the nature of fine dust, which may be carried to immense distances, and a part of which resembles exactly the so-called cosmic dust.

(4) That the same high-pressure gas can fracture, break up, and pound a rock, and afterwards resolidify the same. That in thus resolidifying, the broken-up rock may mould itself accurately on the bounding walls of its enclosure, so as to take their polish and the impress of the striations upon them. And, further, that portions may be thrust outside the apparatus in the form of protuberances of the nature of "eruptive cones." And thus it may be conceived that, by the force of high-pressure gas from below, rocks may be broken up and reconsolidated *in situ* to form breccias of diverse natures.

Some further applications of the experiments may be suggested.

Thus they may perhaps explain the origin of those remarkable natural pits of Hainaut, which have given rise to much discussion. In their general structure these pits are analogous to the diamond pipes of South Africa. Like them they are more or less circular perforations in the rocks, of unknown depth, and filled with rock debris. Since none of the explanations hitherto applied to them seem satisfactory, perforation by high pressure gas may be tried.

Again, in certain of the experiments the faces of the fissures in the cylinders of rock were found to be polished and striated. The polishing and striation of rock surfaces in connection with faults is known as slickensides, and ascribed to the movement of one surface over the other. M. Daubrée's results indicate the possibility that certain slickensided surfaces may rather be due to the energetic action of high pressure gas. In any case it is perhaps a little difficult to understand how a *single* movement of one rock surface over another—if we suppose a fault produced by a continued movement in one direction—could produce anything like a perfect polish. And it cannot be denied that the above experimental result shows the possibility of another cause.

And further, if we accept M. Daubrée's interpretation of his results, we arrive at the remarkable conclusion that gaseous bodies, given sufficiently high pressure and rapid motion, can polish and striate in a way generally supposed to be confined to solid bodies. This, indeed, is in conformity with the general results of advanced physical research which tends to show that, under sufficient pressure, hard and solid bodies can be made to act as liquids, while soft and even gaseous bodies, if endowed with sufficient force and speed, act like solids.

If, then, a gaseous body, under certain conditions of speed and pressure, can polish and striate a rock without the intervention of solid particles, is it not possible that ice, given certain conditions of speed and pressure, may likewise striate and polish without the graving tools usually considered necessary? The conception of an ice-sheet, or glacier, moving over the rock surface of the country with a series of pebbles and boulders firmly frozen into its lower surface is difficult to reconcile with the physics of ice masses in motion. Hence it seems worth while to make a trial application of the experimental results in this direction likewise. Even if we do not accept M. Daubrée's view that the striation of the rock surface was accomplished by the gas alone, and hold that the intervention of solid particles was required, there is still a possible application to glacial action. For if solid particles simply carried along by a rapidly-moving gas can produce parallel striations, may not particles simply carried along by the ice do likewise without being held firmly frozen into its mass? On either view, in fact, a difficulty in the conception of how a glacier striates and polishes is removed.

NOTES.

The professors of the University of Melbourne have interviewed the Premier on the subject of the decrease in the grant to that institution. They said that there was no possibility of reducing the present staff, as it was not overmanned. Many of their number had come to the colony under special contract with the authorities of the university, and it would be a serious matter if faith were broken with them by insisting on a reduction in their salaries. Mr. Patterson replied that these were times of retrenchment, and it was right that everybody should contribute something to pull the country out of its difficulty. It appeared, however, that the University had been cut down £5000 last year, and it was further proposed to reduce the expenditure on the institution by £3000. He reiterated generally the statement made by the Minister of Education on the subject of retrenchment, but he promised to hold a consultation with Mr. Campbell, with the view of ascertaining if anything could be done in the matter. He thought it possible that Mr. Campbell, on taking a review of the special circumstances of their case, might see his way to some abatement of the rigorous course which had been proposed.

A meeting of the Executive Committee of the Rothamsted Jubilee Fund was held on Monday, the Earl of Clarendon in the chair. On the motion of the Chairman, the Duke of Devonshire, as the incoming President of the Royal Agricultural Society of England, was added to the Committee. Sir John

Evans (hon. treasurer) reported that the fund now amounted to £572 13*s.*, that the granite memorial proposed to be set up in front of the Laboratory at Rothamsted was nearly ready, and that the portrait of Sir John Lawes, by Mr. Hubert Herkomer, was in progress. It was decided to request the Minister for Agriculture to preside at the dedication of the memorial and the presentation of addresses to Sir John Lawes and Dr. Gilbert by various learned societies, on Saturday, the 29th inst., at 3 p.m. It was also decided that the fund should not be closed until after the presentation, and subscriptions (not exceeding two guineas) will be received until further notice by Mr. Ernest Clarke, hon. secretary, at 12, Hanover Square.

THE next meeting of the Australasian Association for the Advancement of Science will commence in Adelaide, South Australia, on September 25, 1893, under the presidency of Prof. Ralph Tate, of the University of Adelaide. The Association has been in existence since 1888, and now numbers over 900 members. The four previous meetings, held at Sydney, Melbourne, Christchurch, and Hobart, under the presidencies respectively of Mr. Russell, Baron von Mueller, Sir James Hector, and Sir Robert Hamilton, K.C.B., have been very successful. It is hoped that some visitors from the old country may be induced to attend the coming meeting, where they may count upon a cordial welcome. The time fixed is eminently suitable for visitors; and in previous years the Colonial Governments and the local steamship companies have granted substantial reductions of fares to members of the Association, and it is anticipated that the same privileges will be continued on the present occasion. We may add that at the request of the local secretaries, two former members of the Adelaide University, Prof. T. Hudson Beare, of University College, London, and Prof. Horace Lamb, of the Owens College, Manchester, have underaken to answer inquiries, and to give all information in their power to intending visitors.

DR. ARCHIBALD SANDEMANN, who at one time was Professor of Mathematics at Owens College, Manchester, died at Perth a few days ago. He was seventy-one years of age.

AT a special general meeting of the Geological Society, on June 21, it was decided to have an index prepared to the first fifty volumes of the Quarterly Journal, at an expenditure not exceeding £450. If possible, the index will be issued early in 1895, in two numbers in paper covers, uniform with the Quarterly Journal, and as a supplement to volume fifty.

AT the first meeting of the recently elected Council of the Institution of Civil Engineers the following reappointments were made:—Mr. Hugh Lindsay Antrobus as Treasurer, Dr. William Pole, F.R.S., as Honorary Secretary, and Mr. James Forrest as the Secretary. The Council consists of Mr. Giles, President; Sir Robert Rawlinson, K.C.B., Sir B. Baker, K.C.M.G., F.R.S., Sir Jas. N. Douglass, F.R.S., and Mr. J. Wolfe Barry, Vice-Presidents; Dr. William Anderson, F.R.S., Mr. Alex. R. Binnie, Sir Douglas Fox, Sir Charles Hartley, K.C.M.G., Mr. J. C. Hawkshaw, Mr. Charles Hawksley, Prof. Alex. B. W. Kennedy, F.R.S., Sir Bradford Leslie, K.C.I.E., Mr. James Mansergh, Sir Guilford L. Molesworth, K.C.I.E., Mr. W. H. Preece, F.R.S., Sir Edward James Reed, K.C.B., F.R.S., M.P., Mr. William Shelford, Mr. F. W. Webb, and Mr. W. H. White, C.B., F.R.S.

A MEETING of the Yorkshire Naturalists' Union will be held at Kirkwood, Moorside, on Monday, July 10, for the investigation of the neighbourhood of Donthwaite Dale, Sleightholme Dale, and Kirkdale.

THE curator of the Maidstone Museum has printed and is circulating an Exchange List of duplicate lepidopterous insects contained in the museum. It embraces the Rhopalocera only, and upwards of 5000 specimens are available for distribution. Copies of the Exchange List can be had on application. The housing and proper supervision of duplicate natural history specimens has become in many museums a serious tax upon the ingenuity and time of the curators, and it would seem very desirable that exchange lists should become more general than is the case at present. Their value would be greatly increased, moreover, if for this purpose a uniform system of nomenclature were adopted.

TWO prizes of $150 and $75 respectively will be awarded by the Anthropological Society of Washington at the end of this year for the best essays on the elements that go to make up the most useful citizen of the United States, regardless of occupation. The prizes are open to competitors of all nationalities. While it is not proposed by the Society to limit the scope of the discussion, and while each essay will be considered on its merits by the Commissioners of Award, it is suggested, in view of the character of the Society and the wishes of the donor of the prize fund, that the treatment be scientific, and that the potential citizen be considered (1) from the point of view of anthropology in general, including heredity, anthropometry, viability, physiological psychology, &c.; (2) from the point of view of personal characteristics and habits, such as care of the body, mental traits, manual skill, sense training and specialisation, and all-round manhood; and (3) from the ethical point of view, including self-control, humanity, domesticity, charity, prudence, energy, *esprit de corps*, patriotism, &c. Essays submitted in competition for the prizes should be delivered not later than November 1, 1893, to the Secretary of the Board of Managers of the Society, Mr. Weston Flint, No. 1101 K Street, N.W., Washington, D.C., to whom all correspondence relating to the prizes should be addressed.

WE are requested by the Imperial and Royal Austro-Hungarian Consulate-General to call attention to the charitable foundation instituted by the Sisters Froehlich at Vienna, for making pecuniary grants to persons who have distinguished themselves in art, science, or literature. The grants are made irrespective of nationality, provided that the applicants are resident in Austria. Further information can be obtained at the Imperial and Royal Austro-Hungarian Embassy, 18 Belgrave Square, S.W.

A CORRESPONDENT, writing to the *Pioneer Mail*, says that Murree was visited by a terrific hailstorm on May 28. The hailstones are described as being fully the size of racket balls, and they bounded from the ground to a height of four or five feet. They did a large amount of damage to trees and flowers, and strewed the neighbourhood with small branches and leaves. Numerous panes of glass were broken, and the ground was covered with hail to a depth of between two and three inches.

IN the *Repertorium für Meteorologie* (vol. xvi.) A. Schoenrock describes a remarkable oscillation of temperature at St. Petersburg and neighbourhood on February 11 last. On the 10th the thermometer rose all day, the readings being $-12^\circ{\cdot}1$ F. at 7 a.m., $-0^\circ{\cdot}4$ at 1 p.m., $23^\circ{\cdot}4$ at 9 p.m., and at about 3.45 a.m. of the 11th, $28^\circ{\cdot}4$. At this time the thermometer began to fall very rapidly, the decrease being no less than 23° in the course of a quarter of an hour, and by 7 a.m. it had fallen to $2^\circ{\cdot}6$. The wind, which had been southerly on the morning of the 10th, suddenly changed to east-north-east on the morning of the 11th, the force being light on both days. The phenomenon was to a less extent observed at other stations around St. Petersburg; to the eastward it did not reach beyond Ssermaxa, but the westerly limit could not be determined for want of stations.

A USEFUL discussion of the normal distribution of the rainfall in the Madras Presidency, based on the records of twenty years (1870-89), has been published by C. Benson, Deputy Director of the Department of Land Records and Agriculture. The year has been divided into four periods:—(1) the hot weather, April and May; (2) the south-west monsoon, June to September; (3) the north-east monsoon, October to December; and (4) the dry weather, January to March. And the Presidency has been divided into sixty-four tracts, or groups of stations, lying in physico-geographical areas which showed, on inspection of the records, the greatest similarities. The results of the annual distribution of rainfall, from which we take a few extracts, shows that this selection of areas is correct in principle, and that any general average for the whole Presidency would be, as the author states, misleading in the extreme. Over the greater part of the Presidency the heaviest rainfall is brought by the south-west monsoon; the north-east monsoon only brings any considerable amount along the Coromandel coast. Over the whole of south Canara and in the northern part of the Wynaad the annual fall exceeds 125 inches, and in a portion of the former it amounts to nearly 180 inches. On the coast of Malabar it amounts to from 108 to 117 inches, while further inland, in the same district, it is only about 75 inches. Besides the above localities, it is only on the western slopes of the Nilgiris, where the annual fall amounts to rather over 90 inches, that it anywhere exceeds 70 inches. In a few other localities the rainfall exceeds 50 inches, while it is only over a comparatively small portion of the Presidency that the annual fall amounts to 40 inches, and over a very large section of it it does not reach 30 inches. The dryest section of the Presidency lies in the Bellary and Anantapur districts to the north of Mysore, where the average rainfall does not reach 21 inches.

THERE is perhaps no micro-organism which has been so exhaustively studied as regards its behaviour in water as the *Bacillus anthracis*. The list of memoirs on this subject has moreover been lately increased by the elaborate report just issued to the Water Research Committee of the Royal Society, entitled, "The Vitality and Virulence of *B. anthracis* in Potable Waters," by Percy Frankland and M. Ward. Additional interest and importance must however now be attached to these researches, inasmuch as quite recently this organism has been actually discovered in the mud at the bottom of a well ("Bactéries charbonneuses dans la vase du fond d'un puits," by Diatroptoff, *Annales de l'Institut Pasteur*, March, 1893). An epidemic of splenic fever broke out amongst some sheep on a farm in the South of Russia. Thinking that the disease might be connected with the use of a particular well water, the latter was bacteriologically examined. Diatroptoff was unable to discover the anthrax bacillus in the water, but an investigation of the *mud* at the bottom of the suspected well revealed the presence of an organism, which on inoculation into animals was proved beyond doubt to be the *B. anthracis*. On the well being closed no further cases of anthrax occurred. That the germs of anthrax had in some manner gained access to the well is certain, and opens up the possibility of the communication of this disease by means of drinking water. Moreover the likelihood of such contamination taking place through the drainage from soil, points to the desirability of destroying the carcases of infected animals by cremation rather than by burial.

ACCORDING to Faraday's electrolytic law we ought to obtain the same amount of metal deposited on the anode, for a given current, whatever the composition of the electrodes. However, Dr. Oettel (*Chemiker Zeitung*) finds that with platinum electrodes the deposit of copper is only from 74 to 89 per cent. of that obtained with copper electrodes, the density of the current being 0·13 ampères per square decimetre, and no free hydrogen being liberated. The cause of this divergence is the formation at the anode of persulphuric acid and of hydrogen dioxide, which diffuse in the liquid, and reaching the cathode become reduced, causing a diminution in the quantity of metal deposited. The addition of an easily oxydised body, such as formic acid, annuls the action of these secondary products, and increases the quantity of copper deposited to 98·7–99·6 per cent. of the theoretical quantity. Alcohol is still more efficacious, 99·9 per cent. being obtained.

DR. OETTEL has also investigated the divergences observed in the weight of the deposit in the copper voltameter when an acid solution is employed. The divergences are of such a magnitude that it has been generally recommended to use a perfectly neutral solution, although the resistance is in this case much higher. The author, however, finds that, with a current density less than 0·3 ampères per square decimetre, the neutral solution gives too heavy a deposit. When an acid solution to which alcohol has been added is used, the results agree with those obtained with the silver voltameter. The best results are obtained with a solution consisting of 15 grms. of copper sulphate, 5 grms. of sulphuric acid, and 5 grms. of alcohol mixed with 100 grms. of water, the current density being between 0·06 and 1·5 ampères per square decimetre.

A LETTER from Sir David Salomons appears in the *Electrician* in which he says that when trying some of the experiments shown at the Royal Society *soirée* by Mr. Pike and himself he found that the attraction between two vacuum tubes far exceeded what theory would expect, if due only to static effects, or to the mutual action of one current upon another. Further experiments (though not yet completed) have shown that:—(1) Two vacuum tubes attract one another strongly. (2) The attraction is almost, if not quite, the same, whether they touch one another along the whole length or only at their ends, one of the tubes being dumb-bell shaped. (3) A spiral vacuum tube sucks in a "core" tube like a solenoid does an iron core, and the more the "core" is drawn in the less luminous the "core" tube appears. The core tube in this experiment was not connected to the circuit. (4) When the tubes are placed end on they attract one another and stick together; no repulsion takes place, which would occur if the effect were of a static nature.

MM. SORET AND GUYE have made an investigation to determine the rotatory power of quartz at low temperatures (*Archives des Sciences Physiques et Naturelles*, Geneva, March 15). During the observations, the specimen of quartz was immersed in alcohol, and the temperature of the liquid was determined by noticing the variation in the resistance of a platinum wire, the readings being compared with those given by an air thermometer. The instruments of research were arranged along an optical bench and the order was first a light source, then one of Cornu's polarising prisms. After the collimator came the bath containing the quartz. A Foucault's analyser followed, and last of all was a direct vision spectroscope minus the collimator. The source of light was a vertical sparking-tube having platinum electrodes arranged at the surface of a solution of bromide of sodium. From the experiments it appears that Joubert's formula (*Jour. de Phys.* 1879, viii. 1) represents approximately the rotatory power of quartz for sodium light down to a temperature of about − 70°.

CONSIDERABLE importance can at present be attached to a study of the properties of solutions of salts in different solvents, for such solutions appear to be the most likely to afford evidence as to the validity of the hypothesis of electrolytic dissociation. From measurements on the magnetic rotatory polarisation of solutions of salts in water, alcohol, pyridine, amyl alcohol, and acetone, Herr Schönrock (*Zeitschrift für physikalische Chemie*, xi. 6, 753) concludes that the specific rotation of a salt is independent of the concentration, and of the nature of the solvent, and that there is therefore no evidence of effects which might be attributed to electrolytic dissociation. Dr. Perkin pointed out in 1889 that the molecular rotation of chlorhydric acid calculated from the behaviour of a solution in water was twice as great as the value deduced from a solution in amyl oxide. This result has been employed by the upholders of the "new" theory of solutions as clearly indicating the effect of electrolytic dissociation. Herr Schönrock finds, however, that chlorhydric acid reacts chemically with amyl oxide, and that if allowance be made for this reaction, chlorhydric acid exerts the same effect on polarised light when dissolved in amyl oxide as when dissolved in water. In the same communication values are given for the specific and molecular rotations of some fatty and aromatic hydrocarbons, fatty alcohols, &c., and relations are established between the magnitudes of these constants which are similar to those discovered by Dr. Perkin. The rotations of solutions of double salts are also treated in the paper.

AT a recent meeting of the Berlin Society of Naturalists, Herr Ascherson spoke on the metallic-looking deposit often found on the teeth of ruminating animals in Southern Europe and the East. Hertwig described a silver-like crust on the back teeth of a goat in Xante, as composed of fine lamellæ, and of calcium-carbonate with some iron. In most cases, however, the coating is rather of a gold, bronze, or brass colour, and the yellow pigment is probably of organic origin. It is more common to meet with the deposit on the molars of wild ruminants (especially antelopes) than on those of domesticated animals. Natives of the Mediterranean region say the gold colour is due to eating a mysterious, light-giving plant, very difficult to find, but much desired, as it changes all that it touches to gold, or indicates gold in the ground, or can be used for gold-making. Various plants have been specified as the source of the deposit, one being the Lebanon poppy, the ground leaves of which have a remarkable golden look, very similar to that of goats' teeth, so that a causal relation between the two has seemed natural. Dried remains of the plant, too, have a bright metallic lustre. An examination by Herr Graebner shows the gold colour to have its seat in the moderately thickened cell membranes of the tissues concerned; but the shining look apparently comes from a thick deposit of wax on the epidermis. The teeth of certain fossil ruminants have been found with similar incrustations, *e.g.* molars of Samotherium from the miocene of Mitylene in Samos.

AT the bottom of the valley of St. Martin, near Millau (Aveyron), the Boundoulaou grotto pierces the calcareous rocks of a promontory of the Larzac. There are four entrances on the face of the cliff; the most practicable lies on the western flank at a height of 535 m., and may be reached with the help of a ladder 14 m. long. It was explored last autumn by M. E. A. Martel, who, in conjunction with M. Émile Rivière, describes his finds in the *Comptes Rendus*. It was found to consist of three galleries, one above the other, the lowest of which contained a lake which fed two perennial springs emerging at a point lower down. This lake was explored with great difficulty in a canvas boat under a vault hardly 1 m. high. In the middle of the cave was found a kind of dome 25 m. high and wide, evidently hollowed out by water. In the upper gallery, 15 m. above the level of the lake, the explorers encountered a neolithic bone deposit containing a large fragment of pottery, a well-made cylinder of bone, and seven human skeletons. Three of these were arranged side by side under a sort of shed of rocks, with their heads touching each other. It seemed as if these persons had been surprised and drowned by a sudden flood of the lake below. One of the skulls is that of a young male adult remarkable for the thickness of the cranial bones and for the want of complexity in the sutures. The second complete skull belongs to a subject not completely grown up, and probably of the female sex. Besides these skulls many other human remains were found, including six mandibles, seven humeri and one cubitus, three femurs and five tibias, and one left ilium, amounting in all to traces of seven skeletons. Speaking generally, the type resembles that of the Caverne de l'Homme Mort (Aveyron). An interesting relic also found was a bone cylinder made of the diaphysis of a human femur, and probably representing an amulet or a trophy of war.

A BIOLOGICAL station has been recently started on Heligoland. According to the recent report of the director, Herr Heinke, it contains, with other rooms, six workrooms with excellent light, one for the director, two for the assistants, a fourth for Dr. Kuckuck (who is engaged on the marine flora of the island), while the two others are for "ambulant" naturalists. The conditions of occupation of these will soon be published. The cellar space is being arranged for aquaria. Several boats with dredging and fishing apparatus are at the disposal of the inmates. One of these is a launch with petroleum motor; it has a small cabin, with cooking-stove, &c., so that the whole day can be spent comfortably on the sea. In the summer months arrangements will be made for excursions of several days. A few months' researches on the fauna and flora round Heligoland have revealed a greater richness in these than had been supposed. New forms, not before observed in the German North Sea, have come to light almost daily. The ichthyologist finds Heligoland a rich field; and interesting studies can be prosecuted on the larval forms of crustacea, on mimicry and protective colours in marine animals, and their relations to marine plants, &c.

MR. THOMAS E. BEAN contributes to the *Entomologist* for July the results of a fairly extensive breeding of *Colias christina* and *C. elis*, undertaken with a view of determining whether more male or female butterflies are produced. From seventeen separate broods of *C. christina*, 116 males and 143 females were raised, and nine broods of *C. elis* gave 32 males and 69 females. All the families were subjected to uniform treatment and condition, hence the results show that some cause or causes control the development of sex entirely apart from the influence of variations in nutrition. The sex proportions do not seem to be determined by the seasonal stage at which the eggs are laid, and Mr. Bean thinks that in some cases at least sex is dependent upon antecedent causes, the influence of external conditions not applying.

A NUMBER of special articles contributed to the *Hampshire Observer*, by the Rev. R. H. Clutterbuck, on the Whites of Selborne, Fyfield, and Abbots Ann, will shortly be published at the office of the journal, Winchester.

MESSRS. DULAU AND CO. have just issued parts xxiii. to xxvii. of their catalogue of zoological and palæontological works. They include works on general Entomology, Coleoptera, Diptera, Hemiptera, and Hymenoptera.

MR. JAMES BRITTEN and Prof. G. S. Boulger have reprinted from the *Journal of Botany* their "Biographical Index of British and Irish Botanists." It is largely rewritten, and completed down to the end of 1892, giving the names and other information respecting all British (and Irish *sic*) botanists known to the editors who had died before that time. It contains 1825 names.

THE Ealing Microscopical and Natural History Society has issued its sixteenth annual report. In it are given abstracts of lectures delivered at meetings of the Society during 1892, and some notes on the local forms of *Helix memoralis* and *hortensis*, prepared by Mr. A. Belt. There are few societies in the environs of London that are able to publish such satisfactory reports of their proceedings.

IT is only in a very narrow and restricted sense that statistical information gained by the ordinary census can be accepted as an indication of the educational status of a country. However, an attempt was made to obtain some figures under this head during the census of the colony of Tasmania in 1891. The standards taken was the ability to read and write, to read only, and to be able to do neither. The tabulation of the results of the inquisition shows that the percentage of persons who said they could read and write reached a maximum of 95·04 between the ages of fifteen and twenty, and then decreased gradually to 55·68 for persons of eighty-five years of age and over. Of all the persons whose respective ages were not less than fourteen, 88·77 per cent. could read and write, 3·50 per cent. could read, and 7·73 per cent. avowedly lacked the qualifications for either of those classes.

MR. S. COTTERELL has compiled a little handbook to various publications, documents, and charts connected with the rise and development of the railway system of Great Britain and Ireland. The book is published by Mr. Edward Baker, John Bright Street, Birmingham. It is a compact little bibliography of railway matters, and deserves to be issued in a much better form than it is at present.

Two papers are contributed to the current journals upon the hitherto unisolated tetrachloride of lead. The earlier of the two, by Prof. Classen and Herr Zahorsky of the Aachen laboratory, is communicated to the *Zeitschrift für Anorganische Chemie*. During the course of an interesting series of experiments with liquid chlorine, it was observed that the liquid was entirely without action upon pure lead dichloride, $PbCl_2$, but that in presence of concentrated hydrochloric acid a solution of tetrachloride of lead was produced. Twenty-five grams of lead chloride were placed in two hundred cubic centimetres of fuming hydrochloric acid, and the mixture cooled by means of ice and salt. Liquid chlorine was then added and the vessel closed. After two days the lead dichloride had all disappeared and a homogeneous yellow liquid remained, consisting of a solution of lead tetrachloride in hydrochloric acid. All attempts to isolate the tetrachloride were unavailing, but upon adding ammonium chloride a double salt of the composition $2PbCl_4.5NH_4Cl$ crystallised out. This salt, containing tetrachloride of lead, forms yellow crystals which are quite permanent in closed vessels and withstand a temperature of 100° without change. The crystals are decomposed by water. If only a small quantity of water is added the dichloride separates and a solution of hypochlorous acid is formed. If much water is added a clear brown solution is produced which probably contains plumbic acid, $Pb(OH)_4$; this solution rapidly decomposes with separation of lead dioxide, PbO_2.

THE second paper, by Prof. Friedrich, of Graz, is contributed to the *Berichte*. Prof. Friedrich has succeeded in isolating the pure tetrachloride itself, $PbCl_4$. A solution in hydrochloric acid was first obtained by the action of chlorine gas on lead dichloride suspended in hydrochloric acid. From this the double salt with ammonium chloride was prepared by the addition of sal-ammonia to the liquid product. According to Prof. Friedrich, the composition of this salt is represented by the formula $PbCl_4.2NH_4Cl$. It was obtained in well-defined combinations of the octahedron and cube, and would appear to be isomorphous with the corresponding tin salt, $(NH_4)_2SnCl_6$, the well-known *pink salt* which was formerly so largely used as a mordant for madder dyes. When this double salt containing tetrachloride of lead is placed in strongly cooled oil of vitriol a somewhat energetic reaction occurs, the chloride of ammonium being decomposed with evolution of hydrochloric acid gas. But, strange to say, the tetrachloride of lead is not attacked by concentrated sulphuric acid, and it separates in yellow drops, which finally coalesce to form a heavy yellow liquid, which sinks to the bottom of the vessel. This may be purified by repeated agitation with oil of vitriol, and is eventually obtained after separation as a clear, yellow, very highly refractive, heavy but mobile liquid, which yields numbers upon analysis agreeing with the formula $PbCl_4$, fumes in contact with moist air, and decomposes slowly with separation of lead dichloride and escape of chlorine gas. Upon warming it suddenly decomposes with explosion, the dichloride of lead being produced in the form of a cloud tinted somewhat yellow by the free chlorine. Its specific gravity at 0° is 3·18. At − 15° it solidifies to a mass of yellow crystals. With a little cold water it forms a hydrate, probably $Pb(OH)_4$, which readily decomposes, and with excess of water it yields a precipitate of peroxide of lead PbO_2. When added to a little very cold concentrated hydrochloric acid a crystalline compound, probably of the composition $PbCl_4.2HCl$, is formed. When mixed with oil of vitriol and warmed in a current of hydrochloric acid gas the liquid may be partially distilled. As soon, however, as temperature reaches about 105° explosion occurs, as described above. In this respect, also, lead tetrachloride resembles tetrachloride of tin, which may be distilled without decomposition from a mixture with sulphuric acid.

NOTES from the Marine Biological Station, Plymouth.—Recent captures include large swarms of Salps, the nurses and young chains of *Thalia democratica-mucronata*. From the 15th to the 25th they were very common and in good condition; after the 25th they became reduced in number, and were much injured by the storm which occurred last week. In addition to the above there were observed numbers of *Obelia* and *Thaumantias* medusæ; and from time to time Echinoderm, Annelid, and Müller's larvæ, as well as *Cyphonautes* and the *Eudoxia* larva of *Muggiæa*. The Mollusc *Nassa incrassata* is now breeding.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*, ♂) from India, presented by Mr. W. Henegan; a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mr. J. H. Brown; three Common Marmosets (*Hapale jacchus*) from Brazil, presented by Mr. Hope Gibson; a Brown Bear (*Ursus arctos*, ♀) European, presented by Mr. F. Collier, F.Z.S.; two Wild Swine (*Sus scrofa*, ♂ ♀) from North Africa, presented by Mr. Jasper A. Mathews; a Purple Heron (*Ardea purpurea*) British, presented by Mr. R. Heywood; a Leadbeater's Cockatoo (*Cacatua leadbeateri*) from Australia, presented by Mrs. Anna Margaret Hills; a Guilding's Amazon (*Chrysotis guildingi*) from St. Vincent, W.I., two Tree Boas (*Corallus hortulanus*) from Grenada, W.I., presented by the Hon. Sir Walter Hely-Hutchinson, K.C.M.G.; a Brazilian Cariama (*Cariama cristata*), a Barn Owl (*Strix flammea*), a King Vulture (*Gypagus papa*), a —— Buzzard (*Buteo* sp. inc.) from Brazil, presented by Mr. Howard C. Wolfe; an Illiger's Macaw (*Ara maracana*), two yellow-headed Conures (*Conurus jendaya*) from Brazil, two Rufescent Teguexins (*Tupinambis rufescens*) from Mendoza, deposited; six European Beavers (*Castor* ——) from the river Rhone, France, eight Garganey Teal (*Querquedula circia*), six Common Teal (*Querquedula crecea*) European, purchased; a Thar (*Capra jemlaica*, ♂), two Black-headed Gulls (*Larus ridibundus*) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMET FINLAY (1886 VII.).—M. Schulhof, in the current number of the *Astr. Nach.* (3171) gives the new elements and ephemeris of Comet Finlay. They are as follows :—

$$
\begin{array}{rcl}
M & = & 6^\circ\ 58'\ 5''{\cdot}33 \\
\pi & = & 7\ 41\ 34{\cdot}1 \\
\Omega & = & 52\ 27\ 42{\cdot}7 \\
i & = & 3\ \ 2\ \ 2{\cdot}1 \\
\phi & = & 46\ \ 0\ 49{\cdot}4 \\
\mu & = & 535{\cdot}8046 \\
\log.\ a & = & 0{\cdot}5473335
\end{array}
\left.\begin{array}{l} \\ \\ \\ \end{array}\right\} 1893{\cdot}0 \ (\pi, \Omega, i)
$$

A BRIGHT COMET?—In a note under this heading which appeared in these columns on June 22, we gave an interpretation of a telegram from Kiel to one of the German Observatories. The message ran: "From Boston probably bright comet photograph, Lewis, 5 June, 09571 ; Boston 26423, 07558, 43552 ; 12 June, 10043 ; Boston 27119, 06904, 44066. Verbatim ventilate unpliable."

Unfortunately, after having translated the code on a separate sheet of paper, we set down the Boston times as the right ascensions, an error often liable to occur when one is used to reading right ascensions in hours, minutes, and seconds, and not in degrees of arc.

This telegram was distributed only to a few observatories in order to substantiate the discovery, or otherwise, before the announcement was openly made, and it was in the endeavour to present our readers with this piece of news as early as possible that this clerical error was made.

STARS WITH REMARKABLE SPECTRA.—In *Astronomische Nachrichten*, No. 3171, Mr. T. E. Espin continues his list of stars with remarkable spectra (*Astr. Nach.* 3090), the number amounting now to 736. The places are all brought up approximately to 1900.

THE PERIOD OF ROTATION OF VENUS.—It was hoped that the pure telescopic observations of the surface of Venus would settle the question of the period of rotation, but the results show that we are not yet in possession of the absolute value as can be gathered from a comparison of Schiaparelli's work with Trouvelot's, and Löschardt's and Wislicenus determinations. A method, apparently not yet tried, is that suggested by Egon von Oppolzer (*Astr. Nach.* 3170), which involves the use of the spectroscope for the determination of the motion in the line of sight. By comparing the spectra of opposite points on the equator, he says it might probably be possible to determine the time of rotation. Cassini de Vico's assumption involves a velocity for an equatorial point of somewhere about 473 metres per second, so that we should expect to get a motion, indicated in the spectrum by the displacement of the lines, of about 946 metres, or roughly, one kilometre. This motion, he thinks, can with our present means of measuring be made apparent, and we should thus decide between Cassini de Vico's assumption and Schiaparelli's 225-day period.

THE NEWALL TELESCOPE.—The report of the work done with the Newall refractor (*Camb. Univ. Reporter*, June 20) shows that during the past year the work was severely handicapped by the fact that the driving clock was undergoing repair. Last summer the objective prisms were adjusted, and about eighty stellar spectra were obtained, sixteen of which are of use for measurement ; but later the driving worm had to be dismounted and sent to Dublin. Using a single prism, the spectrum beween F and H is 2 inches long. In a photograph of Vega with an exposure of nine minutes the hydrogen lines up to ζ (Huggins's notation) were obtained, the spectrum between F and ζ being 3 inches in length. With both prisms the dispersion is very great, the spectrum more than covering the length of the photographic plate used (length between Hγ and H is 1·75 inches). The necessity of having to send the driving worm of the new clock away to be re-cut, in addition to making several instrumental tests, seems to have taken up much of the time that might have been used in observing. The fifth satellite of Jupiter is within the reach of this instrument, and has been seen on two occasions, January 24 and February 4, Mr. Newall remarking that "it has been most justly described as a very difficult object."

JOHNSTON'S NOTES ON ASTRONOMY.—Under this title we have before us a small book, by Swift P. Johnston, edited by James Lowe, consisting of about eighty pages, dealing with the more purely elementary mathematical portion of astronomy. The book is a compromise between a popular work and a textbook for students, and links the one to the other. Coming out originally in the form of notes, the present edition has been widely expanded, and may now be said to form an excellent course of astronomy for beginners. It is simple-worded and concise, and presents the reader with a general sketch of the more important problems which is the part of the science of astronomy to solve. The diagrammatical figures supplement and render more clear various parts of the text, and the 150 excellent questions, if fully answered by the reader, would prove a very serviceable addition to his astronomical education.

THE HODGKINS FUND PRIZES.—The following prizes are announced by the Smithsonian Institution with the intention of furthering the wishes of Mr. Thomas Hodgkins, who we have previously referred to as having presented a large donation to the institution for the "increase and diffusion of more exact knowledge in regard to the nature and properties of atmospheric air in connection with the welfare of man" :—

(1) \$10,000 for a treatise embodying some new and important discovery in regard to the nature and properties of atmospheric air. These properties may be considered as bearing upon all or any of the sciences, *e.g.* not only in regard to meteorology, but in connection with hygiene, or with any department whatever of biological or physical science.

(2) \$2000 for a satisfactory essay on : (*a*) The known properties of atmospheric air considered in their relationship to research in every department of natural science, and the importance of a study of the atmosphere considered in view of these relationships. (*b*) The proper direction of future research in connection with the imperfections of our knowledge of atmospheric air, and of the connections of that knowledge with other sciences. The essay as a whole should tend to indicate the path best calculated to lead to worthy results in connection with the future administration of the Hodgkins foundation.

(3) \$1000 for the best popular treatise upon atmospheric air, its properties and relationships (including those to hygiene, physical and mental). This essay need not exceed 20,000 words in length.

All these treatises may be written in English, French, German, or Italian, and sent to the secretary of the Smithsonian Institute, Washington, before July 1, 1894, with the exception of those in competition for the first prize, which will be delayed until December 31, 1894. Further information on the above and other points, such as the giving of medals, &c., may be obtained from the secretary's report, and also from *Astronomy and Astrophysics*, No. 116, p. 560.

GEOGRAPHICAL NOTES.

AT the meeting of the Royal Geographical Society, held on June 26, Captain F. R. Maunsell gave an account of his journeys in Kurdistan during the summer of 1892. Kurdistan is not an accurately-defined province, but may be described as the extensive district inhabited by the Kurds, embracing the region of Lake Van and the Upper Euphrates, as well as the country between the Tigris and the Persian frontier south of Lake Van. Captain Maunsell entered Kurdistan from the north, passing Erzingan and Erzerum, and skirted the eastern shore of Lake Van. The watershed between the lake and the Tigris Valley is very low, but it is not easy to discover any place at which there might at some former time have been an outlet. It seems not unlikely that a lava overflow from the volcano Mount Nimrud, on the western shore of the lake, cut off the plain of Van from the Tigris, and thus formed the lake. Captain

Maunsell descended to the Tigris, and followed that river to its mouth, making excursions into the mountainous country to the east. Only in southern Kurdistan is the population exclusively Kurdish. North of Mosul there is a considerable Christian element. Not many years ago Kurdistan was a separate province, ruled over by Kurdish beys, whose strongholds were Amadia, Rawanduz, Sulaimanie, and other places. But all this is changed, and the country is now under the direct control of Turkish officials. The original Kurdish organisation was tribal, and the prevailing habits of the tribes are still nomadic and pastoral, but have been modified by local conditions. Thus, the Kurds of the mountainous district north of Lake Van remain in villages all through the severe winter, the great distance being a bar to migration into a warmer plain country. In the summer, however, they leave their village dwellings for their tents, which they often pitch close to their winter home. In the rugged Dersim country the Kurds are perforce sedentary. In central and southern Kurdistan the tribes have easy access to the Mesopotamian plain, and a large number of them live in tents all the year round.

AT a special meeting of the Royal Geographical Society held on Monday at London University, Burlington House, it was decided, by 172 to 158 votes, that it was inexpedient to admit ladies as ordinary Fellows of the Society.

A DALZIEL'S telegram says that Lieutenant Peary, with Mrs. Peary and twelve companions, left New York on July 2 in the whaling barque *Falcon*, on his second expedition to the Arctic regions.

MUSEUMS ASSOCIATION.[1]

I.

THE Museums Association is one of the youngest of the numerous social organisations which it is thought expedient at the present day to constitute in order to give facilities for the interchange of ideas on subjects interesting to a special group of men. It is, indeed, only in the fourth year of its existence, and this is the first time that a meeting has been held in London, the centre in which are gathered the great national collections, and in which reside so considerable a number of persons engaged in their custody. The association claims York as its birthplace, and Liverpool, Cambridge, and Manchester have in succession afforded it hospitality and enjoyed the advantage of its presence.

We all meet with one object in view. We are all impressed with the value—with the necessity, I should say—of the Museum (using the word in its widest sense, as a collection of works of art and of nature) in the intellectual advance of mankind.

How could art make any progress, how could it even exist, if its productions were destroyed as soon as they were created; if there were no museums, private or public, in which they could be preserved and made available to mankind then and thereafter? How could science be studied without ready access to the materials upon which knowledge is built up? In many branches of science the progress is mainly commensurate with the abundance and accessibility of such materials.

Though the first duty of museums is, without question, to preserve the materials upon which the history of mankind and the knowledge of science is based, any one acquainted with the numerous succession of essays, addresses, lectures, and papers which constitute the museum literature of the last thirty years must recognise the gradual development of the conception that the museum of the future is to have for its complete ideal, not only the simple preservation of the objects contained in it, but also their arrangement in such a manner as to provide for the instruction of those who visit it. The value of a museum will be tested not only by its contents, but by the treatment of those contents as a means of the advancement of knowledge. Though this is the general consensus of opinion, as expressed in the literature just referred to, there is naturally still much divergence as to the best methods by which this ideal may be carried out, and there are still many practical difficulties to be overcome before the views so ably advocated on paper can be reduced to the test of actual performance. It is with a hope of assisting in the solution of these difficulties that this Association has been founded.

If in the few words with which I am expected to preface the real work of the Association I shall be found to dwell too exclusively upon the subject of natural history museums, I must apologise to many friends and members of the Association who are present. It must be distinctly understood that under the word museum we include collections of all kinds formed for the advancement of any branch of knowledge, except those specially devoted to books, which already are cared for by the "Libraries Association"—on the model of which ours was formed. I hope that in our papers at this meeting and in future presidential addresses we shall have all branches of museum work fairly represented.

It is my fate to have been born what is commonly called a "naturalist." I hardly remember the time when I was not a possessor of a museum, but it always took a distinctly biological direction. Hence, although by no means unappreciative of other branches of museum work, I shall confine myself chiefly to that part of the subject upon which I can speak from personal experience. Even in this branch time will compel me to limit myself to observations upon some of the larger questions connected with our subject, leaving details for discussion in our subsequent meetings.

One great difference between the work of the curator of an art museum and that of one devoted to what are called natural history subjects, is that in the case of the former the specimens he has to preserve and exhibit come into his hands very nearly in the condition in which they will have to remain. A picture, a vase, a piece of old armour, or a statue, beyond a certain amount of tender care in cleaning and repairing, which is more or less mechanical in its nature, is ready for its place upon the museum shelves. But this is far from being the case with the greater number of natural objects. Not only do they require special methods of preservation, but very often their value as museum specimens depends entirely upon the skill, labour, patience, and knowledge expended upon them. In specimens illustrating biological subjects the highest powers of the museum curator are called forth. A properly mounted animal or a carefully-displayed anatomical preparation is in itself a work of art, based upon a natural substratum. In few branches of museum work has there been greater progress in late years than in this, and few offer still further scope for development.

Partly from this cause, and partly from the fact that art has for a longer period and to a greater degree engaged the attention of civilised man than nature, the method of preservation, arrangement, and exhibition of works of art are on the whole further advanced than are those of natural objects. But no one can deny that there is still in many galleries devoted to the exhibition of works of art of various kinds great room for improvement. There is generally far too great crowding; too many objects so placed that the tallest man cannot see them properly, even when standing on tiptoe; too many others placed so low that they can only be examined by lying down on the floor; too many completely spoiled by the juxtaposition of other incongruous objects, or by unsuitable settings. It is only in a very few public museums (I may instance as a conspicuous example the splendid museum of antiquities at Naples) that the immense advantage to be gained by ample space and appropriate surroundings in aiding the formation of a just idea of the beauty and interest of each specimen contained in it can be properly appreciated. Correct classification, good labelling, isolation of each object from its neighbours, the provision of a suitable background, and above all of a position in which it can be readily and distinctly seen, are absolute requisites in art museums as well as in those of natural history. Nothing detracts so much from the enjoyment and advantage derived from a visit to a museum as the overcrowding of the specimens exhibited. The development of the new museum idea to be spoken of later on will be one way by which this can be remedied in the public galleries; but if museums are what they ought to be, and what I venture to believe they will be in the future, the question of space on a considerably larger scale than has hitherto been thought of will have to be faced. This is of course mainly a matter of expense, and after all but a small matter compared with expenditure now considered necessary in other directions. There are persons who think the country made a tremendous effort in building so much as is yet finished of the new Natural History Museum in the Cromwell Road, and shake their heads at the expenditure

[1] Address of the President, Sir William H. Flower, K.C.B., F.R.S., &c. London Meeting, July 3, 1893.

asked for either to complete that establishment by the erection of the wings at the sides, or to finish the neighbouring South Kensington Museum in such a manner as worthily to hold its collections, both of art and science; or who would deprecate the further expansion of the magnificent series of treasures of ancient and mediæval art in the British Museum at Bloomsbury, of which the country has such just reason to be proud. Let such persons consider that the largest museum yet erected, with all its internal fittings, has not cost so much as a single fully-equipped line-of-battle ship which in a few years may be either at the bottom of the sea, or so obsolete in construction as to be worth no more than the materials of which it is made. Not that I am deprecating the building of ships necessary for our protection, but rather wishing to show that the cost of such museums as are still required for the proper education of the nation is not such as would produce any sensible impression upon its financial position.

I may make a still more apposite comparison, and point to the vast sums of money spent by this nation upon the whole subject of education now and a few years ago. The total estimate for what is called "Class IV., Education, Science and Art," for the financial year 1883-84, amounted to £4,748,556. In ten years it has grown to nearly double that amount, the estimate for 1893-94 being £9,172,216, the increase being mainly due to what is termed "Public Education." The amount spent upon the development of museums is comparatively insignificant. The British Museum vote (including the library and the natural history branch) has only increased from £146,019 to £157,500. The cost of the various museums maintained by the Science and Art Department shows little appreciable augmentation, except in the case of that at Dublin, where I am glad to see £19,035 is now put down instead of the £13,602 of the former period. Compared with the whole amount expended upon other methods of education, national expenditure upon museums and art galleries is at present very small.

In reference to this subject one cannot help considering how much might have been done if only a moderate portion of that large sum of money obtained a few years ago by the tax on brewers, and handed over to the County Councils to spend in promoting technical education, had been used for erecting museums, which might have taken a permanent place in the education of the country. Every subject taught, in order to make the teaching real and practical, should have its collection, and these various collections might all have been associated in the county museum under the same general management. The staff of teachers would assist in the curatorial work, and thus a well-equipped central college for technical education might have been formed in every county, sending out ramifications into the various districts in which the need of special instruction was most felt, and being also the parent of smaller branch museums of the same kind wherever they seem required.

But it is not only in the buildings that the expense of the museums of the future will have to be met. Another great advance will have to be made before they can be placed upon a satisfactory footing, and perform the functions that can be legitimately expected of them. This is in the elevation of the position and acquirements of those who have the care of them. As I have said on a previous occasion, "What a museum really depends upon for its success and usefulness is not its building, not its cases, not even its specimens, but its curator."

Speaking in the presence of a number of gentlemen who are curators of museums, do not let me be misunderstood. I do not mean that you are not zealous in the cause and make great sacrifices for it, and do all you can under the often difficult circumstances in which you are placed; but what I mean is—and I am sure you will one and all agree with me when I say it—you are not properly appreciated by the public, and the importance and difficulties of your position are by no means sufficiently understood. In a civilised community the necessities of life, to say nothing of luxuries (which we do not ask for), but the bare necessities of a man of education and refinement, who has to associate with his equals, and bring up his children to the life of educated and refined people, involve a certain annual expenditure, and the means afforded by any occupation for this necessary expenditure gives a rough and ready test of the appreciation in which such occupation is held.

Now, a curator of a museum, if he is fit for his duties, must be a man of very considerable education as well as natural ability. If he is not himself an expert in all the branches of human knowledge his museum illustrates, he must be able to understand and appreciate them sufficiently to know where and how he can supplement his own deficiencies, so as to be able to keep every department up to the proper level. His education, in fact, must be not dissimilar to that required for most of the learned professions. Still, manual dexterity and good taste are also most valuable. He must, in addition, if he is to be a success in his vocation, possess various moral qualifications not found in every professional man—punctuality, habits of business, conciliatory manners, and, above all, indomitable and conscientious industry in the discharge of the small and somewhat monotonous routine duties, which constitute so large a part of a curator's life. Such being the requirements of the profession, let us see what are the inducements offered to men to take it up as a means of livelihood. I really am sorry to have to speak of such a sordid subject, but I know it is one you naturally shrink from talking of yourselves. You would be the last people in the world to take the remedy, so often now resorted to by other classes, into your own hands. A strike of curators is hardly to be contemplated. Remember, now, that I am not speaking of this subject in your interests, or the interests of any individuals. Whether any of you personally should have your emoluments, your social position, your opportunities for good, improved, is not now with me an object of concern, it is in the interest of that great question, the advance of the museum as a means of educating, cultivating, and elevating mankind, that I am speaking, an advance that can only be effectively made when the curatorship of a museum is looked upon as an honourable and desirable profession for men of high intellectual acquirements.

Let me take a few examples of the inducements to enter this profession at the present time. I have before me some recent advertisements. The curator of the Museum of the Philosophical and Literary Society of one of the largest and most flourishing of our manufacturing cities is offered £125 a year for his services. In another town, smaller and less wealthy, it is true, "a resident curator, meteorological observer, and caretaker, is wanted for the museum and library buildings at a salary of £50 per annum, with rooms, coal, and gas. Applicants are to state age and scientific qualifications."

In a recent newspaper discussion upon the establishment of a museum in one of the midland counties, after it had been pointed out that one of the prime necessities of such an institution was a provision for the maintenance of a curator, a leading gentleman of the district, a zealous and sympathetic advocate of the cause, perfectly acquiescing in this view, suggested that £100 a year should by all means be set aside for this purpose.

It is frequently my lot to be consulted by anxious parents of sons who develop a taste for museum work as to what such a taste will lead to if cultivated. I need hardly say that, however much I may wish our ranks to be recruited by such enthusiastic aspirants, boys often of great ability and promise, I cannot conscientiously offer much encouragement. The best I can say is that I hope things will be better in the future than they are at present. As far as the Metropolis is concerned there has been some improvement, and I think that indications are not wanting that this improvement will continue and extend.

I have referred at the beginning of this address to the great amount of recent literature upon the museum question, consisting chiefly in depreciation of the old ways of arranging museums, of suggestions for the improvements for the future, and mainly in the development of what may be called the new museum idea. What this idea is was tersely expressed nearly thirty years ago by the late Dr. John Edward Gray, in his address to the British Association at Bath (1864) as President of Section D, when near the close of his long career as administrator of a collection which by his exertions he had made the largest of the kind in the world, he laid down the axiom that the purposes for which a museum was established were two—"first, the diffusion of instruction and rational amusement among the mass of the people, and, secondly, to afford the scientific student every possible means of examining and studying the specimens of which the museum consists." He then continued—"Now, it appears to me that in the desire to combine these two objects, which are essentially distinct, the first object—namely, the general instruction of the people—has been to a great extent lost sight of and sacrificed to the second without any corresponding advantage to the latter, because the system itself has been thoroughly erroneous."

This was a remarkable admission, coming from a man who had been brought up in, and had acted throughout the whole of his life upon, the old idea; but it clearly expressed what was then beginning to be felt by many who turned their unbiassed attention to the subject, and it is the keynote of nearly all the museum reforms of recent date. During the long discussion which followed, the new idea found powerful advocates in Huxley, Hooker, Sclater, Wallace, and others; but Owen, whose official position made him the chief scientific adviser in the construction of the new National Museum of Natural History, never became reconciled to it, and, unfortunately, threw all the weight of his great authority into the opposite scale.

The method of application of this principle depends entirely upon the general nature of the museum, whether that of a nation, a town, a school, or a society or institution established to cultivate some definite branch of knowledge. It is mainly of national museums that I am speaking at present, and it is only in national museums that the fulfilment of both functions in fairly equal proportions can be expected. In almost all other museums the diffusion of knowledge or popular education will be the primary function, and if the true principles of arrangement of such museums be once grasped, this is a function which can be carried out upon the largest or the smallest, or any intermediate scale, according to the means of the institution and requirements of the locality.

The collections for the advancement of science, on the other hand, are of value mainly in proportion to their size, and no museum at present existing has come anywhere near what is required for the exhaustive study of natural history. If any one were now to endeavour to write a complete monograph of any family in the animal kingdom, he would search in vain for materials for doing so, not only in any one museum, but in all the museums in the world put together.

Soon after the arrival in our Natural History Museum of the great and carefully selected and labelled collection of Indian birds, presented by Mr. A. O. Hume, containing upwards of 60,000 specimens, a well known ornithologist commenced the volumes devoted to birds in the excellent series of manuals on the fauna of British India, edited by Mr. Blanford. I am told that when he began the work he was seen sitting at his table rubbing his hands with delight at the prospect of success in his labours guaranteed by such an unprecedented mass of material. But after a few weeks the scene had changed. He was pacing up and down the room, wringing the same hands in despair at the hopelessness of solving the tangled problems of the variation according to age, sex, season, and locality, the geographical distribution, and the limits and relationship of any single species, owing to the absolutely insufficient number of properly authenticated specimens at his command. Every zoologist will recognise this as a scarcely exaggerated description of what he meets with at every step of his work. Except, perhaps, for some special and limited groups, which may be taken up in private collections, a national museum alone can possibly attempt to bring together the materials required for such exhaustive work, but it is undoubtedly the duty of all national museums to endeavour to do this. There should be in every great nation one establishment at least where problems may be attacked with some prospect of success, and the only conditions upon which collections for this purpose can be maintained are that they should be so arranged as to occupy the smallest possible space compatible with their proper preservation and convenience of access; and that they should be removed from all the deteriorating influences of light and dust, and at the same time be perfectly available for the closest examination by all those whose knowledge is sufficient to enable them to extract any information from them. This means that they cannot be *exhibited* in the ordinary sense of the word; although it must not be supposed that they are on that account in less need of orderly and methodical arrangement. There is certainly a danger of collections which are not generally exhibited becoming neglected, and degenerating into the condition of mere accumulations of rubbish. Anything of the kind is absolutely incompatible with the true requirements of specimens kept for research. They specially need to be arranged in an orderly and methodical manner, and to be thoroughly well catalogued and labelled, so that each may be found directly it is wanted, and to be frequently inspected to see that they are free from moth or other deleterious influence. The object of keeping them in this condition is, indeed, that they should be preserved and not destroyed, as many exhibited specimens ultimately are. Much curatorial ingenuity may be exercised in the methods of stowing and arranging such specimens to the best advantage. The conditions of access to them will be precisely those now accorded to books or manuscripts in a library, prints and drawings in an art museum, the records and public documents in the Rolls Office or Somerset House.

As the actual comparison of specimen with specimen is the basis of zoological and botanical research, and as work done with imperfect materials is necessarily imperfect in itself, it is far the wisest policy to concentrate in a few great central institutions the number and situation of which must be determined by the population and resources of the country, all the collections (especially those containing author's types or the actual specimens upon which species have been established, and which must be appealed to through all time to settle vexed questions of nomenclature) which are required for the prosecution of original research. It is far more advantageous to the investigator to go to such a collection, and take up his temporary abode there while his research is being carried out, with all the material required at his hand at once, than to travel from place to place and pick up piecemeal the information he requires, without opportunity of direct comparison of specimens.

On the other hand, in local museums, such collections are not only not required, but add greatly to the trouble and expense of the maintenance of the institution, without any compensating advantage. Here it will be the duty of the curator to develop the side of the museum which is educational and attractive to the general visitor, and to all who wish to obtain that knowledge, which is the ambition of many cultivated persons to acquire without becoming a specialist or expert. The study of the methods by which such museums may be made instructive and interesting offers an endless field for experiment and discussion, and the various problems connected with it are treated of not only in the literature I have referred to, but in a more practical manner in many museums in various parts of the world.

Without pursuing this question further at the present time, I should like to repeat from a previous address on the same subject[1] certain propositions which are fundamental in the arrangement of collections of the class of which I am now speaking.

The number of the specimens must be strictly limited, according to the nature of the subject to be illustrated, and the space available. None must be placed either too high or too low for ready examination. There must be no crowding of specimens one behind the other, every one being perfectly and distinctly seen, and with a clear space around it. If an object is worth putting into a gallery at all, it is worth such a position as will enable it to be seen. Every specimen exhibited should be good of its kind, and all available skill and care should be spent upon its preservation, and rendering it capable of teaching the lesson it is intended to convey. Every specimen should have its definite purpose, and no absolute duplicate should on any account be admitted. Above all, the purpose for which each specimen is exhibited, and the main lesson to be derived from it, must be distinctly indicated by the labels affixed, both as headings of the various divisions of the series and to the individual specimens.

(*To be continued.*)

MARINE BIOLOGICAL ASSOCIATION.

THE report of the Marine Biological Association of Great Britain was read at the annual meeting of the Association held in the rooms of the Royal Society on June 28. From it we learn that the buildings, fittings, and machinery of the Plymouth laboratory are in a satisfactory condition, and have not necessitated any special outlay.

The question of the boats has occupied the council very seriously during the past year. The old steam-launch *Firefly* is still at work, although it was decided to replace her a year ago. A new steam-launch, of about the same size as the *Firefly*, was recently purchased, but has proved to be unsuitable for rough work. The little sailing-boat, *Anton Dohrn*, is in excellent repair, and continues to be very useful.

The need of a deep-sea-going boat has become most pressing, but there are no funds in hand sufficient for its purchase and maintenance. This need has been particularly felt of late in the fishery inquiries in which the Association has been engaged in the North Sea as well as at Plymouth.

The type-collection is increasing satisfactorily under Mr. Garstang's care. In addition to the specimens at Plymouth, a

1 British Association for the Advancement of Science. Report of Newcastle Meeting, 1889.

series of selected specimens has been arranged and exhibited at various *soirées*. This exhibition series is being enlarged.

Owing to the generosity of Mr. J. P. Thomasson, who has made a second donation of £250 for this purpose, it has been possible for the council to retain the services of Mr. Holt for fishing inquiries in the North Sea for a second year.

Mr. Garstang has been appointed for a second year to superintend the collection, preservation, and supply of material. The character of the specimens supplied by the laboratory has improved very greatly under his care.

Mr. Cunningham has continued his observations on the rate of growth and probable ages of young fish, a paper on which was published in the November number of the Association's journal. He has also continued his experiments on the colouration of the under-side of flat-fishes. Since Christmas he has been occupied in an inquiry into the question of the destruction of immature fish, the first results of which appear in the May number of the journal.

Mr. Cunningham has also succeeded in artificially fertilising the eggs of the flounders which he has reared in the laboratory tanks during the last three years from a length of half an inch; the eggs developed, and the larvæ were artificially fed for ten days after the absorption of the yolk-sac. This result is of great importance and interest.

Mr. Holt has been at work now for eighteen months upon an investigation of the fisheries of the North Sea, and his papers in the journals for November and May supply a large amount of important information. The Council contribute to the expenses of the Cleethorpes Aquarium of the Marine Fisheries Society (Grimsby) in return for Mr. Holt's use of their laboratory and tanks.

Mr. Garstang has captured a large number of rare forms during the past year, and he has added five new species to the list of the British fauna. As a result of his work during the past year, an intimate knowledge of the localities of the fauna has been acquired, so that specimens can be obtained without delay.

The receipts for the past year include the annual grants from H.M. Treasury (£1000) and the Worshipful Company of Fishmongers (£400); annual subscriptions have produced £160, composition fees £16, the rent of tables at the laboratories, £34, the sale of specimens £205, and the admission to the tank-room £70, the total amounting, with lesser sums, to £2199.

The Vice-Presidents, Officers, and Council proposed by the Council for 1893–94 are:—President: Prof. E. Ray Lankester, F.R.S.; Vice-Presidents: The Duke of Argyll, K.G., K.T., F.R.S., the Duke of Abercorn, K.G., C.B., the Earl of St. Germans, the Earl of Morley, the Earl of Ducie, F.R.S., Lord Walsingham, F.R.S., Lord Revelstoke, the Right Hon. A. J. Balfour, M.P., F.R.S., the Right Hon. Joseph Chamberlain, M.P., Prof. G. J. Allman, F.R.S., Sir Edward Birkbeck, Bart., M.P., Sir Wm. Flower, K.C.B., F.R.S., the Right Hon. Sir John Lubbock, Bart., M.P., F.R.S., Prof. Alfred Newton, F.R.S., Sir Henry Thompson, Rev. Canon Norman, F.R.S., Captain Wharton, R.N., F.R.S.; Council—elected Members: F. E. Beddard, F.R.S., Prof. F. Jeffrey Bell, Prof. W. A. Herdman, F.R.S., Sir John Evans K.C.B., F.R.S., A. C. L. G. Günther, F.R.S., Prof. A. C. Haddon, Dr. Sydney J. Hickson, Prof. W. C. McIntosh, F.R.S., Right Hon. E. Majoribanks, M.P., E. B. Poulton, F.R.S., P. L. Sclater, F.R.S., Adam Sedgwick, F.R.S., Prof. Charles Stewart, Prof. W. F. R. Weldon, F.R.S., Hon. Treasurer: E.L. Beckwith; Hon. Secretary: G. Herbert Fowler.

THE CONDITIONS DETERMINATIVE OF CHEMICAL CHANGE.[1]

NOTWITHSTANDING the large amount of evidence now placed on record that substances commonly supposed to be capable of directly interacting do so only in the presence of at least one other substance, chemists do not appear to have arrived at any clear and consistent understanding of the conditions determinative of chemical change: as each fresh case is recorded, we continue to express surprise, overlooking the fact that Faraday, in his early "Experimental Researches in Electricity," clearly foresaw what the conditions were, and that but a slight extension of his generalisations is needed to frame a comprehensive theory. The subject is of such importance that it appears to me desirable to discuss the bearing of recent observations, especially as they to some extent necessitate the modification of views that I have expressed elsewhere, and in order to attract the attention of physicists, to whom we must now look for guidance in these matters.

Eight years ago, in the course of the discussion on Mr. H. B. Baker's communication on combustion in dried gases (Proc. Chem. Soc., 1885, 40), I defined chemical action as *reversed electrolysis*: in other words, in order that chemical action may take place, it is essential that the system operated on comprise an electrolyte. I then pointed out that as neither hydrogen nor oxygen was an electrolyte, a mixture of only these two gases should not be explosive; and, moreover, as water was not an electrolyte, and it was scarcely probable that water and oxygen or hydrogen would form an electrolyte, it was difficult to understand how the presence of water pure and simple should be of influence in the case of a mixture of hydrogen and oxygen. This forecast has since been verified, the remarkable series of experiments carried out by V. Meyer in conjunction with Krause and Askenasy having clearly demonstrated that the formation of water from hydrogen and oxygen takes place at an irregular rate, and is, therefore, dependent on the presence of a something other than water—I imagine an acid impurity. But this is a consideration which has not yet received the proper attention, and it is, therefore, desirable to emphasise its importance by reference to other cases. Mr. Baker's recent preliminary note on the influence of moisture in promoting chemical action (*ante*, p. 229) affords several interesting examples:—Thus, he states that neither does hydrogen chloride combine with ammonia, nor is nitric oxide oxidised by oxygen if moisture be excluded. In the former case, the addition of water should suffice to determine the combination, as water and hydrogen chloride together form a "composite electrolyte" (*cf.* Roy. Soc. Proc., 1886, No. 243, p. 268); as neither nitric oxide nor oxygen, however, forms a composite electrolyte with water, in this case water alone should not determine the occurrence of change; but if, by the introduction of a trace of "impurity" in addition to water the presence of a composite electrolyte were secured (however high its resistance, owing to the smallness of the amount of "impurity"), action would set in, and when once commenced would proceed at an increasing rate, as nitric acid would be formed and the resistance of the electrolyte would consequently diminish. On this account it will be a task of exceeding difficulty to experimentally demonstrate that nitric oxide and oxygen are inactive in presence of water alone; but there can be no doubt that such must eventually be admitted to be the case, provided always that it is permissible to extrapolate Kohlrausch's observations, and to conclude from them that *pure* water is a dielectric. The gradual increase in the rate of change here contemplated corresponds to the period of induction observed by Bunsen and Roscoe in their observations on the interaction of chlorine and hydrogen; the statement recently made by Bodenstein and V. Meyer (*Berichte*, 1893, 1146) that a mixture of chlorine and hydrogen behaves irregularly on exposure to light is a valuable confirmation of Pringsheim's observations, and there is now no room for doubt that *pure* chlorine and hydrogen would be incapable of interacting. That no such irregularity is observed on heating iodine with hydrogen is not surprising, as hydrogen iodide would be formed from the very outset, and the electrolyte present would exert a minimum resistance almost at once. There is, however, a significant difference in the behaviour of the two mixtures, as hydrogen chloride should behave as hydrogen iodide, so that the problem is but incompletely solved: it may be that the one mixture was more nearly pure than the other, or it may be that the formation of hydrogen chloride from hydrogen and chlorine, under the influence of light, is dependent on the presence of some particular substance, together with water, and does not take place under the influence of any substance capable of forming a composite electrolyte with water; probably, however, the difference observed is chiefly due to the fact that only one of the actions is reversible under the conditions prevailing in the experiments.

Lastly, attention may be directed to the formation of sulphuric oxide from sulphurous oxide and oxygen, which is readily effected in presence of a catalyst, such as finely divided platinum; it cannot be supposed that the mere presence of platinum would condition the occurrence of change, and doubtless moisture is also necessary, the platinum or other catalys

[1] Reprinted from the Proceedings of the Chemical Society, No. 125.

but serving to promote the oxidation of the sulphurous oxide at a temperature considerably below that at which sulphuric oxide decomposes when heated. The action of surfaces generally may well be of this character, and the converse influence they so frequently exercise is probably an effect of the same order.

I have elsewhere raised the question whether there may not be a difference between actions taking place under the influence of low and of high electromotive forces—whether water, *per se*, may not be an electrolyte towards high, although not towards low, forces, in the case of high temperature changes, or those brought about under the influence of the electric spark, for example. More attentive consideration of the subject has led me to think that this is not the case, and that we must treat high temperature changes such as occur and are involved in gaseous explosions in the same way as those occurring under ordinary conditions and at low temperatures. From this point of view, Mr. Baker's statement that ammonia and hydrogen chloride do not combine is of extreme importance; the formation of ammonium chloride from these two compounds apparently involves no interchange, but a mere combination of two substances each endowed with considerable "residual affinity," and there is no reason why a distinction should be drawn between such a case and that afforded by, say, *atoms of hydrogen and oxygen*, the difference being, it would seem, one of degree only; in fact, I am no longer inclined to believe that atoms are capable of directly uniting. In all cases at least one function of the (composite) electrolyte would appear to be that of providing the necessary "mechanism" whereby the degradation or discharge of the energy is effected. If this argument be sound, its logical extension involves the conclusion that *pure* gases should be dielectrics, *i.e.* that the passage of an electric discharge through a gas like that of an explosive wave through, say, a mixture of hydrogen and oxygen, can only take place if an electrolyte be present. Hitherto but little attention has been paid to the electric discharge in gases which have been highly purified. The peculiar behaviour of Tesla tubes referred to by Mr. Crookes in the discussion on Mr. Shenstone's paper on the formation of ozone is, perhaps, explicable from this point of view—it may be that the atmosphere within the tube does not become conducting until sufficient moisture and "impurity" have been projected from its sides. It is conceivable that a similar explanation may hold good in the case of Prof. Schuster's observation, that it is possible to urge a current of low electromotive force across a gas subjected to a high electromotive force in itself insufficient to cause a discharge in the gas; the atomic dissociation hypothesis put forward in explanation of the phenomenon does not appear to me to be sufficient.

Finally, the question arises, Can no line be drawn; are no two pure substances capable of combining or interacting:—For example, water and sulphuric anhydride? There is little to guide us here, but it seems not unlikely that water has special properties which enable it to act directly; moreover—perhaps because—in such cases composite electrolytes would result. Ammonium chloride, so long as it remains solid, is clearly a compound of a different order, and it may well be that compounds of this type are in no case directly obtainable from their constituents, because, under the conditions under which they are formed, they cannot behave as electrolytes.

Apparently, in all cases in which molecular aggregates are formed—as in the case of solutions—we are dealing with dissociable and dissociating systems, and it is not improbable that we may ultimately find an explanation of the mechanism of such changes in this fact.

At present there is no information forthcoming whether simple electrolytes, such as fused silver chloride, for example, will condition chemical change in the way that water does—whether, for instance, silver chloride will condition the formation of hydrogen chloride from chlorine and hydrogen, so that a gas battery might be constructed of these three substances.

HENRY E. ARMSTRONG.

THE SUCCESSION OF TEETH IN MAMMALS.

PROF. H. F. OSBORN, in the *American Naturalist* for June, gives an account of recent researches upon the succession of the teeth in mammals. He says:—

"The recent studies of Kükenthal, Röse, and Taeker in the discovery of the complete double or milk dentition in the Marsupials, and in the discussion of its relation to that of the reptiles, also in the ontogenesis of the crowns of the teeth among the Cetaceans, Edentates, Primates, and Ungulates are of the greatest interest and importance. They involve a complete revolution in our ideas as to the interpretation of the dentition in the three orders first mentioned above."

After giving an account of the work done by the European observers, Prof. Osborn shows, by means of a table, the phylogenetic order as observed by Cope and Osborn, and the ontogenetic order as observed by Röse and Taeker. His researches indicate that the earliest forms of mammals were homodont, and had two or more series of successional teeth. Then within the mammalian stem the teeth were differentiated, and there arose a great heterodont group with teeth at least of three kinds—incisors, premolars, and molars, all successional. From the most anterior premolar arose the canine. Then came the division between the Marsupials and the Placentals, the former tending to suppress the development of the second series of teeth, the latter retaining the second series as far back as the first molar. There is an obvious advantage in the line of succession being drawn at the first molar,[1] for upon the molars rested the necessity of complex development, and such development was best effected in permanent crowns.

1. All the so-called "milk molars" plus the so-called "true molars" constitute the *first series*. Beneath one or more of the "true molars" in lower mammals are rudiments of a second series. The *second series* consists therefore of these submolar rudiments plus the successional or permanent premolars, incisors and canines.

2. In the stem Marsupials the entire first series persisted and became mainly permanent (non-deciduous); the second series became rudimentary and non-successional with the exception of the fourth upper and lower premolars, and possibly one or two other teeth which either replaced or were intercalated between members of the first series. One or more premolars were suppressed, and one more molar retained than typical in the Placentals. Thus is explained the apparently atypical dental formula of Marsupials.

3. In the stem heterodont Placentals (excepting the Cetacea and Edentata) the entire first series persisted, and all the incisors, canines, and premolars remained deciduous. The successional second series persisted as far back as the first molar.

4. In the stem Cetacea the entire first series persisted, and the second series became rudimentary and non-successional. The tooth form changed from a heterodont to a homodont type.

5. In the stem Edentates, which also transformed from the heterodont to the homodont type, the first series became rudimentary, and the second series persisted in the succession even behind the region of the first molar.

Finally, there is evidence that a primitive succession in the region of the molar teeth, lost in the Marsupials and in the Placentals, was more or less fully retained in the Cetacea and Edentates.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Governors of the Glasgow and West of Scotland Technical College have appointed Mr. W. H. Watkinson, lecturerer on engineering, Central Higher Grade School, Sheffield, to the Chair of steam, steam engines, and other prime movers, recently instituted in the college. By several important changes, the engineering department has been recently re-organised, Prof. Jamieson devoting his attention entirely to electrical engineering, Prof. Rowden to mechanics (theoretical and applied), Prof. MacSay to machine drawing, and Prof. Watkinson to the subjects stated above. With this addition and rearrangement the college now possesses an engineering staff worthy of one of the greatest engineering centres in the kingdom. Many additions are wanted, however, to bring the laboratories and general equipment to a position of equality with those even in many provincial towns.

[1] The law of molar evolution is that complication is most rapid in teeth which are longest in use. Thus the first molar is the most progressive tooth of the true molar series, and the last premolar is the most progressive of the premolar series. The apparent exception that the third milk premolar is always an advance type of the third permanent premolar is explained by the fact that the milk premolars are formed to assume the molar function

We have received from the Cambridge University Extension authorities the detailed programme of their summer meeting. Courses of study extending over a month (from July 29 to August 26 inclusive) have been arranged, intended primarily for those connected in some way with the University Extension Movement, though all members of the teaching profession and other students are also admitted. Though the full course extends over a month it has been arranged that those who can only spare a fortnight shall have a fairly complete course of work to go through. The subjects on which instruction is offered are extremely varied, including history, literature, and language, art, economics, and natural science. On the scientific side several courses of laboratory work are provided and in addition there are to be a set of lectures illustrating, from the history of several sciences, the progress and methods of natural science. The services of Sir Robert Ball, Sir Henry Roscoe, and a number of other well-known lecturers have been secured. Many intending visitors will be glad also to see that the authorities have not forgotten that August is a time for recreation as well as study and have made special arrangements for boating, for admission to college gardens, as well as for several excursions to places of historic, artistic, or scientific interest. Three colleges have agreed to board students at extremely moderate rates, and there is an abundance of lodgings. The total expense of the month for a student living economically need not exceed £6 or £7. There are probably not many other ways in which such a pleasant and profitable holiday can be spent for so small a sum.

THE following elections to natural science scholarships at Oxford have been announced:—Mr. H. C. H. Carpenter, of Eastbourne College, to a Natural Science Postmastership at Merton College. Mr. T. J. Garstang, of Manchester Grammar School, to a Natural Science Scholarship at Corpus Christi College. Mr. Richard Warren, of the Charterhouse, to an Open Natural Science Scholarship at New College. In each case the value gained is £80 per annum.

SUMMER courses seem to be the order of rhe day. The Marine Biological Laboratory at Woods Holl, Massachusetts, was opened on June 1, and will remain open until August 30. The Laboratory has aquaria supplied with running sea-water, boats, a steam launch, collecting apparatus, and dredges. There are thirty-three private laboratories for investigators, and five general laboratories. Short courses has also been arranged in zoology and botany, the laboratory work in each case being accompanied by lectures. Every facility is given for the obtain- of general knowledge, while those who are prepared to begin original work, under the guidance of instructors, are provided for as well as the practised investigator. This classification of workers into three grades is an excellent one and well worthy of imitation.

COL. SIR CHARLES W. WILSON, F.R.S., has been appointed Honorary Master of Engineering of the University of Dublin.

SCIENTIFIC SERIAL.

American Meteorological Journal, June.—The principal articles are: Note on the relation of solar spots to terrestrial anticyclones, by A. Searle. The relation considered is not one of cause and effect, but simply an analogy recently suggested in the *Astronomische Nachrichten*, by E. von Oppolzer, whose idea is to substitute the anticyclone instead of the cyclone as is usually done, as the terrestrial term of the comparison. The author considers the comparison to be both striking and plausible, but Prof. Davis thinks it should be limited to terrestrial anticyclones during winter nights.—A new series of isanomalous temperature charts, based on Buchan's isothermal charts, by S. F. Batchelder. The author has constructed a new set of isabnormal charts, based on the observations of the *Challenger* expedition, which are said to show more plainly than those of Humboldt and Dove the departures from the average temperature of a parallel of latitude. The cold area on the west coast of South America is found to be 10° too cool, instead of 6°·7; that on the west coast of Africa to be 6° instead of 4°·5. The excess of heat of Southern Alaska is given as 10° instead of 6°·7, and the south coast of Norway (under the influence of the Gulf Stream) is found to be 23° over the average for the latitude, instead of 20°·3, while the cold areas in the interior of North America and Asia, given as 11°·3 by Dove, are now shown to be 14° below the mean temperature of their latitude.—Proposed subjects for correlated study by State Weather Services, by W. M. Davis. The non-telegraphic records are almost entirely reduced in an arithmetical manner, suitable for the determination of climate, but not for the determination of unperiodic factors of the kind with which weather changes are concerned. The author suggests that all observers should make hourly records of the ordinary weather elements on certain days, that these observations should be charted for every hour, and afterwards consolidated on a single map for the whole country, by which means some extremely interesting illustrations of weather phenomena would be gained, and give a better knowledge of processes now imperfectly understood.—Meteorology as the physics of the atmosphere, by W. von Bezold. This concluding part deals more especially with observations made in balloons, and with thermometer exposure. The author thinks it probable that Dr. Assmann's aspirator will show that the temperatures hitherto made in balloons are affected by radiation to the extent of 10° at least. He also gives some valuable advice as to the observation of clouds, and draws especial attention to the importance of observing not only their outward appearance, but more particularly their formation and dissolution, so as to establish their classification and nomenclature upon a natural basis.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 8.—"The Experimental Proof that the Colours of certain Lepidopterous Larvæ are largely due to modified Plant Pigments, derived from Food." By E. B. Poulton, F.R.S.

The object of this investigation was to afford a conclusive test as to the theory, previously submitted by the author, that some of the colours of certain Lepidopterous larvæ are made up of modified chlorophyll derived from the food-plant.

Larvæ from one batch of eggs laid by a female *Tryphæna pronuba* were divided into three lots fed (in darkness) respectively throughout their whole life upon (1) green leaves, (2) yellow etiolated leaves, and (3) white mid-ribs of cabbage. The larvæ fed upon (1) and (2) became green or brown as in nature, thus proving that etiolin, no less than chlorophyll, can form the basis of the larval ground-colour. Those fed upon (3), in which neither chlorophyll nor etiolin was accessible, were entirely unable to form the green or brown ground-colour. The production of dark superficial cuticular pigment was, however, unchecked. One of the larvæ fed in this way was perfectly healthy, and had become nearly mature when it was accidentally killed. Many others died early, but resembled that last described in the inability to form a ground-colour.

The experiment seems to leave no doubt as to the validity of the conclusions previously reached. Interesting questions as to the changes passed through by the derived pigments are suggested by this inquiry.

"The Menstruation of *Semnopithecus entellus*." By Walter Heape, Balfour Student at the University of Cambridge. Communicated by Prof. M. Foster, Sec. R.S.

"Researches on the Structure, Organisation, and Classification of the Fossil Reptilia. Part viii. On further Evidences of *Deuterosaurus* and *Rhopalodon* from the Permian Rocks of Russia." By H. G. Seeley, F.R.S.

Royal Meteorological Society, June 21.—Dr. C. Theodore Williams, President, in the chair.—Mr. R. H. Scott, F.R.S., read a paper on fifteen years' fogs in the British Islands, 1876–1890, which was a discussion of the fog observations made at the stations which appear in the *Daily Weather Report*. From the observations it appears that there is no trace of a regular increase either in the monthly or in the annual curve. All that can be said is that taking the three lustral periods of five years each, the last of these, 1886–90, comes out markedly the worst, the successive totals being 262, 250, 322.—A paper on upper currents of air over the Arabian Sea, by Mr. W. L. Dallas, of the Indian Meteorological Office, was also read, in which it is shown that there exists a regular arrangement in the vertical succession of the upper currents, and that the Doldrum region, and not the geographical equator, is really the dividing line between the currents of the northern and southern hemispheres.

PARIS.

Academy of Sciences, June 26.—M. Lœwy in the chair.—On the employment of Lagrange's equations in the theory of impact and percussions, by M. Paul Appell.—Theoretical calculation of the inferior contraction in weirs with thin walls and sheets free below, when this contraction attains its greatest values; with experimental verifications, by M. J. Boussinesq.—Formation of natural phosphates of aluminium and iron; phenomena of fossilisation, by M. Armand Gautier. Aluminium phosphate was formed in the Minerva grotto by the action of ammonium phosphate, resulting from the destruction of a bank of guano, upon a subjacent layer of hydrargilite. This action is easily reproduced experimentally. It is even possible to form a small quantity of aluminium phosphate by the prolonged action of ammonium phosphate upon kaolin. Iron phosphates are produced by the action of ammonium phosphate upon spathic iron ore. This is probably the usual origin of vivianite. It is shown that the simultaneous formation of ammonia, sulphuretted hydrogen, and other products of slow bacterian fermentation, with the action of the air dissolved in water, gives rise, in strata at the same time calcareous and ferruginous, to the simultaneous production of lime phosphates and of pyrites.—Note by M. Daubrée accompanying the presentation, in the name of its authors, of the geological map of European Russia.—Observations of the planet Charlois (1893 Z) made with the 14-inch equatorial of the Bordeaux Observatory by M. L. Picart.—On the maximum modulus which a determinant can attain, by M. Hadamard.—Experimental determination of the constant of universal attraction, and of the mass and density of the earth, by M. Alphonse Berget.—On the third principle of energetics, by M. H. Le Chatelier. The laws of the conservation of mass, of momentum, of quantity of electricity, of the centre of gravity, &c., can be embodied in a single law as follows: The individual "energy capacities" of an isolated system are constant, except that of heat (entropy) which increases in irreversible transformations. This "energy capacity," so termed by Ostwald, is made up of several factors of the type of those enumerated above.—On the employment of mercury in potential equalisers by flow, by M. G. Gouré de Villemontée.—Research on the dielectric constants of some biaxial crystals, by M. Ch. Borel. The principal constants of five rhombic and ten clinorhombic substances were determined by finding their axes of polarisation and measuring their periods of oscillation in a uniform electric field, and also measuring the attraction along each axis of polarisation. The crystals were cut in the shape of spheres. The attraction method was like that used by Boltzmann, except that his bifilar balance was replaced by a unifilar quartz fibre balance. Most of the substances examined were double sulphates. A redetermination of the constants for rhombic sulphur showed a closer agreement with Maxwell's law than Boltzmann's results.—On a new method of directly transforming alternating into direct currents, by M. Charles Pollak.—On the combinations of oxalic acid with titanic and stannic acids, by M. E. Pechard.—Researches on the chlorosulphides of arsenic and antimony, by M. L. Ouvrard.—Action of carbonic oxide upon sodammonium and potassammonium, by M. A. Joannis.—On the combinations of boron bromide with the bromides of phosphorus, by M. Tarible.—On the action of zinc and magnesium on metallic solutions and on the estimation of potash, by MM. A. Villiers and Fr. Borg.—Observations on a marine miocene randannite of the Limagne d'Auvergne, by M. Paul Gautier.—The duration of excitability of the nerves and muscles after death is much greater than is generally believed, by M. A. d'Arsonval. This may be shown by means of the myophone, a kind of microphone arranged so as to indicate small muscular contractions. The instrument gives indications of muscular excitability in a rabbit even ten hours after death.—Remarks on M. d'Arsonval's paper, by M. Brown-Séquard. The fact that a muscle under the influence of complete cadaveric rigidity, remaining perfectly inert under the influence of the strongest impulses provoking contraction, is capable of rhythmic motor actions when its nerve is excited, is one of the most interesting discoveries in the physiology of nerves and muscles.—Sketch of the principal anatomo-pathological types of adult chronic gastritis, by M. Georges Hayem.—Observations on ice, made during the cruise of *La Manche*, by M. G. Pouchet.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Elements of Psychology: Prof. J. M. Baldwin (Macmillan).—Everybody's Guide to Music: J. Booth (Saxon).—A Handbook on the Steam-Engine: H. Haeder, translated by H. H. P. Powles (C. Lockwood).—Murray's Handbook—Switzerland, Savoy, Piedmont, 18th edition (Murray).—University Correspondence College Calendar, 1892–93 (London).—Worked Examples in Co-ordinate Geometry (Clive).—A Biographical Index of British and Irish Botanists: J. Britten and G. S. Boulger (West, Newman).—Foundations of the Atomic Theory (Alembic Club Reprints, No. 2): Dalton, Wollaston, and Thomson (Edinburgh, Clay).—Im Reiche des Lichtes, Sonnen, Zodiakallichte, Kometen: H. Gruson (Asher).—Hourly Meteorological Observations made at the Madras Observatory, January, 1856, to February, 1861 (Madras).

PAMPHLETS.—Sir J. B. Lawes and the Rothamsted Experiments: C. M. Aikman (Glasgow).—U.S. Department of Agriculture: Reports of Observations and Experiments in the Practical Work of the Division (Washington).—Traces of Glacial Man in Ohio: W. H. THURSDAY, JULY 13, 1893.

ORDER OR CHAOS?

THE question as to how the vast mass of scientific work which is now annually produced can be most readily sifted and utilised is a matter of pressing importance. There are two opposite types of scientific men who fail in achieving all of which they are capable, because they respectively pay too much and too little regard to the work of their predecessors and contemporaries. The one class are pre-eminently students. Masters of the past history of their subject, they are familiar also with its latest developments, but in the effort to know what others have done, they not unfrequently exhaust energies which might have been better spent in adding to knowledge. To such men a well-ordered scheme for bringing the results of research into a small compass would be a most valuable boon. Of the other type are those who declare, "I never read; if I want to know a thing it is easier to find out all about it in the laboratory than in the library." Whether this is so or not is largely a question of temperament, but there is no doubt that as matters now stand the task of repeating work which has already been done is often less distasteful and scarcely more wasteful of time and energy than the effort to discover if the question has been previously attacked, and if so, by whom and with what results.

In providing for the future it must be remembered that the art of scientific investigation is now taught at many educational centres. Students are turned out by the score who are not only capable of using ordinary laboratory instruments to good effect, but who have taken part in original research. Within a year or two they settle down as masters in schools, mechanics' institutes, or "Polytechnics," or are absorbed in some branch of technology. Whether or no they are to spend their lives in a dull routine of teaching or testing, falling gradually further and further behind the times, or whether they are to aid or even to follow the advance of knowledge depends largely upon the facilities for acquiring information which are afforded to them. They leave the University, or the University College, with its well-stocked library, and forthwith their touch or want of touch with the outer world depends almost entirely on the periodic literature of the science to which they have devoted themselves.

Such persons constitute a class which has only lately come into existence, which will increase largely in the future. Their wants must be considered if any improvement in the organisation of our scientific publications is taken in hand. It follows naturally from the spread of scientific education that the results of scientific study must be made more accessible than heretofore. It is not only the leisured amateur or the distinguished Professor who "knows the ropes" who are to be provided with ready access to knowledge. If a man who does not believe that his student days are over when he leaves college has the right of *entrée* to some first-rate library, and is free from the calls of business at the hours when it is open, he may study modern science there. If he remembers or can easily find out in what volume of the "Phil. Trans." or *Wiedemann's Annalen* the paper he requires was published, if he or his bookseller knows who to write to for a separate copy, and lastly, if he can afford the money to buy it, it is no doubt possible even when far from libraries to bring together the literature of any given subject. It is, however, contended that in all this there is an unnecessary waste of time and trouble, that there ought to be a recognised index, in which references to all that was known on any particular point at some given date are collected, and that each science should be served by some single journal or group of journals with clearly defined functions, in which all that is required in the description and publication of the results of later inquiry may be found.

The letter from Mr. Swinburne, which we published recently, thus raises a larger issue than that with which he chiefly dealt. The Royal Society has for some decades published an admirable name index to scientific literature. The task is rapidly growing beyond the powers of a single society, or indeed of a single country. It is only by the munificence of a wealthy and public-spirited Fellow that it can be carried on at all. Has not the time come when there should be an International Bureau, engaged on a full subject-catalogue, divided into separate parts devoted to different sciences so that the student of any one of them might obtain at a moderate cost an index to past research on his subject?

As regards the question chiefly discussed by Mr. Swinburne, viz. the publication of papers on Physics, it may perhaps be laid down that there are three classes of papers which require different treatment. First are those which should be published in full. They are at present found in the Philosophical Transactions and Proceedings of the Royal Society, in the *Philosophical Magazine*, in the Proceedings of the Physical Society, in the Reports of the British Association, and in the Transactions of the Cambridge and the Manchester Philosophical Societies. To these may be added the journals of the principal Scotch and Irish societies, with which for the present we do not deal. The same author not unfrequently publishes the same facts several times over in several of these periodicals, or publishes fragments of what is practically one series of researches in different journals. No greater state of chaos can be imagined.

Where a man publishes depends not upon the convenience of his readers, but upon whether his paper is ready in March for the Royal Society, or in September for the British Association, upon whether he cares more for a discussion at the "Physical" than for the honours of large type and quarto pages in the Transactions; upon whether he dreads anticipation, or is content to make the leisurely announcements which prove that he has the field to himself.

The second class of papers are those which are only worth publication in abstract. The Royal Society occasionally adopts this form of publication, but other societies for the most part either accept or reject a paper *in toto*.

The third class of paper is that which is a criticism or discussion of what is known rather than a description of an original research. At present these appear chiefly in the *Philosophical Magazine* and in our own columns. It is, however, with regard to the first two classes that the need for organisation is most keenly felt, and as Mr. Swinburne points out, the attitude of the Royal Society is of prime importance. Many would regret if the Society to which the "Principia" was communicated ceased to publish physical work, and indeed if we know anything of the feelings of English Physicists, we do not think that such a catastrophe is probable. On the other hand, it is impossible not to recognise the fact that the Royal Society is an obstacle to the realisation of a satisfactory scheme for the publication of English physical papers.

The Physical Society was founded because at that time the Royal Society offered no facilities for the experimental illustration of communications made to it. The meetings of both the elder and the younger society are fully occupied with the work now undertaken, in spite of the fact that the discussions at the meetings of the Royal Society are short.

If to-morrow all English physicists were to agree to send all their work to the Royal Society there would not be time to discuss it, and many of the papers thus offered, though worthy of publication, would be regarded as not of the type which the Society affects. Yet if there is to be organisation, if order is to succeed chaos, it can only be either by a friendly struggle between the Royal and the Physical Societies, which would not be likely to lead to any definite result at present, or by still more friendly co-operation between them, by which all that is desired might be attained in a few months. That going forward or standing still are alike difficult is undeniable. It is obvious that the conditions which apply to physics apply to other branches of natural knowledge. We shall be glad if those most closely interested will try to smooth the way by discussion in our columns.

THE CAUSES OF GLACIAL PHENOMENA.

The Glacial Nightmare and the Flood: a Second Appeal to Common Sense from the Extravagance of some Recent Geology. By Sir Henry H. Howorth, K.C.I.E., M.P., F.R.S., F.G.S., &c., &c. (London: Sampson Low, Marston and Co., 1893.)

IT is not uncommon to find that men who have devoted much time and careful research to the elucidation of complex phenomena have experienced all the phases of thought through which a succession of previous observers have passed in bringing the subject to its then present stage. This is more usual in certain classes of inquiry than in others, and in such it is clearly helpful to dwell upon the history of the development of opinion upon the question. It is giving, as it were, the embryology of an idea in order to enable the reader to understand better the adult form. In the volumes before us Sir Henry Howorth has rendered this good service to students of glacial phenomena.

The title of the book is unfortunate and may prejudice many against what is really a scientific work of great value.

Sir Henry first gives a sketch of the views of the earlier writers who referred all the phenomena in question to the action of water; then he explains how by degrees the agency of icebergs was called in; how it was next considered that larger glaciers would account for most of the facts; and how, after that, it was supposed that they were to be explained only on the hypothesis of great ice-sheets extending south from either pole, even to the tropics, according to some.

These ice-sheets must, of course, be accounted for by exceptional agencies, such as secularly-recurring astronomical combinations, in connection with which the author discusses the obvious inference that there must have been similar combinations and similar results in previous ages. He then devotes almost the whole of another volume to the various incidental theories which have grown up round the theory of circumpolar glaciation, or are necessary to it, and, finally, admitting a moderate extension of glaciers, he sums up in favour of stronger and more widely extended marine action than has of late been generally admitted.

As we read we cannot but learn to admire the shrewd observation of the older geologists, though the true explanation of the phenomena had not yet been put forward. We see how the obvious suggestion that great rushes of water would account for it all, set Von Buch and Hopkins to calculate what depth and velocity of water would be required to obtain force necessary to transport the blocks perched on the hills; and if there were difficult cases which made some of the "Champions of Water," such as Mierotto, De Luc, and Hall call in the aid of icebergs, still there was the fact that a great deal of the drift appeared to be sorted by water, and that, in great floods, boulders several feet in diameter have been hurried along the rocky bed of a stream with a noise like thunder; that large stones are often tossed by the storm waves to the top of precipices on our western rock-bound coast, as may be seen on a smaller scale where single stones are thrown on to a pier or promenade, though the sea-wall may be almost vertical. The gravel carried by a spate over the meadows is just like that found in the Esgairs, and is thrown up on either side of the torrent in long ridges. There is no doubt that a great deal of what is included in the drift, especially in Germany, is just like what is carried by flood water. It would not be comfortable to feel that the great old heroes of geology advocated views impossible in physics and unsupported by observation. Whether better explanations may in many cases now be offered is another question.

When it was once admitted that the glaciers were formerly much more extensive, and the drift round mountain regions was referred to their agency, it is easy to see how the impossibility of accounting for the occurrence of glaciers in North Germany, where what was thought to be similar drift was widely spread, led to speculation as to the possible extension of ice-sheets from high latitudes all over north-western Europe and north-eastern America, and the views of Bernhardi and Schimper, which involved an ice-sheet coextensive with the distribution of the drift began to be received with favour.

After this was given up as the *direct* cause, it was still held that its *indirect* effects would be very potent in producing extremes of climate alternately in the north and south hemispheres. The question now naturally arose whether there were any recurring glacial conditions in past times, and evidence of such action was seen in rounded surfaces and striated stones from various ancient rocks.

But most of the examples were from localities where the included fragments had been crushed against one another by earth movements, the grooves running alike across the included pebbles and the matrix in which they were imbedded. Or they were from the neighbourhood of what had been mountain ranges repeatedly through long ages. Even if we admit that some ancient conglomerates appear to have derived their boulders from glacial debris, that does not make the conglomerates glacial, but only requires glaciers in the adjacent mountains then as now. On the hypothesis of the geographical origin of glacial conditions, seeing that there must have been elevations and submergences over and over again, glacial phenomena should recur near the areas of upheaval, only without that periodicity which is required by the astronomical theory. There is, moreover, in the fossil flora and fauna no evidence of the recurrence of widespread glaciation such as would justify our referring it to a glacial epoch.

The astronomical glacialists further hold that not only were there secularly alternating periods of cold and heat in either hemisphere throughout the ages, but that within each period there were shorter periods of greater and less intensity of cold, of which we find evidence in the so-called interglacial beds of Britain, and in such deposits as those of Dürnten, where glacially striated pebbles underlie lignite which is covered also by morainic debris. But all advocates of the geographical explanation suppose that the earth movements on which it depends were discontinuous and subject to considerable oscillation, while the advance and retreat of glaciers, as a mere weather result, is so marked that we may safely admit that, as a climatic result of oscillations of level, it might be quite as great as required by any of the cases referred to.

Croll says that by far the most important of all the agencies, and the one which mainly brought about the glacial epoch, was the deflection of ocean currents, but he does not show that it is not possible to account for this deflection by earth movements.

There is one very important fact which does not seem to be generally recognised, namely, that the last glacial conditions extended only over a limited area on either side of the North Atlantic, and that this limitation must be referred to geographical causes, so that, if these were sufficiently powerful to determine the area, they may account for the glaciation itself. "What is wanted, however," our author remarks, "is not testimony to sporadic glaciers or local ice action, but to widespread glacial phenomena such as would witness an ice age."

The absurdity of the answer that percolating water must have removed ice markings from the surface of the stones is sufficiently obvious to any one who has had his attention called to the much finer markings on fossils, &c., which have been preserved.

The grooved stones of Devonian Age in Victoria are worth about as much as the facetted stones from Gorplitz by Barna, which are supposed to prove the great southerly extension of glacial action in Germany, but which more probably owe their form and condition to blown sand.

Several ingenious explanations have been offered of the occurrence of marine shells in stratified drift on the high ground of southern Sweden and northern England and Wales. The more obvious explanation is, of course, that they were left there as the shingly shore of the receding post-glacial sea. But this would have involved earth movements in comparatively recent times to so great an extent as would lend probability to the theory of such elevations as would account for glaciers in temperate regions, and of such submergences as would explain the widespread post-glacial sands and gravels. Some therefore suggested that these masses had been scraped up from the sea bottom and been pushed up the mountains to their present position; that they were, in fact, part of a great terminal moraine of the polar ice-sheet. Some got over the difficulty of explaining the even stratification and the ripple marks on the beds, as well as the non-Arctic character of the shells, by supposing that the sand and shells were pushed up in the ice from the sea bed in temperate regions, but that the deposit in which they are now seen was washed from the ice-foot at these several elevations by the fresh water due to the melting of the ice, and bearing away with it the mud, sand, and stones transported so far in the ice.

Too much stress must not be laid upon stratification and lines of boulders in the drift, as this may be produced by iceberg loads being thrown down in deep water; just as when a handful of mixed sand and grit of various form and different coarseness is dropped into a long glass of water, the larger grains will, *cæteris paribus*, reach the bottom first, and a rough stratification will be produced. The contortion of clays and sands can often be explained by the loads of debris carried by icebergs and dropped upon them, squeezing the underlying plastic mass away, and rolling up the surrounding layers in every variety of fold and crumple.

Our author lays great stress on the fact that there is now no polar ice-cap at all, and that all the evidence shows that the pole is not, and never has been, the centre of greatest cold or of greatest glaciation. The ice radiated from Scandinavia, not from the pole, and the pillars and prominent unglaciated rocks of Northern Asia show that there has been no ice sheet there in recent ages.

In his advocacy of a considerable submergence in comparatively recent times our author has the support of Prof. Prestwich, who, in the last number of the Proceedings of the Royal Society, has expressed the opinion that the masses of unstratified rubble commonly found resting on the slopes and terraces along the English Channel seem to be due to a force of propulsion for which the hitherto generally-suggested causes are manifestly inadequate. He extends his generalisation over Western Europe and the coasts of the Mediterranean, and arrives at the conclusion that the loess was a sediment deposited from the turbid sea-waters during the submergence, while the superficial deposits called "head" he refers to the surface debris swept off by divergent currents during the subsequent upheaval. Both of these movements he refers to periods of such short duration that large numbers of animals were simultaneously drowned and the waters were rendered so turbid as to be unsuited for marine life.

Our author explains many of the phenomena of the later drift by reference to a great submergence, but, wishing apparently to imply that it was of a still more transient nature, speaks of it as a great flood. His flood deposits are not, however, the same as those referred to by Prof. Prestwich.

Sir Robert Ball has pointed out that if the heat received in winter is distributed over thirty-three more days, instead of only over seven more, the result would be glacial conditions in the northern hemisphere, a result which has been somewhat modified by Mr. Hobson, who pointed out that the heat received over the regions within the Arctic circle should be omitted from the calculation.

But the opponents of the astronomical theory are prepared to admit that when we are dealing with operations in which the effects are so obviously cumulative and the reaction of one on the other so important, we may expect in climate, as there are in what we call weather, times of such unstable equilibrium that, for instance, a slight prolongation of the period of cold, which may be small in itself, may yet cause a local change, the effects of which may eventually become very far-reaching—as, in the case of weather, rain may be produced by the explosion of a small quantity of dynamite in the upper regions of the atmosphere. It is useless to deny the existence of such causes as those on which the advocates of the astronomical theory chiefly rely any more than we should deny the possibility of the detection of tidal action in one of the American lakes, because we are convinced that the real cause of the rise of six feet or so of water on one side is due to the gale which we observe blowing across the lake. Nor are we justified in rejecting the possibility of more or less rapid submergences resulting in a rearrangement of surface debris or even in more cataclysmic action of the same kind, as was seen in the earthquake wave that rolled in on Lisbon.

We do seem to require some simpler theory than that of the extreme glacialists to explain the phenomena of the Pleistocene Age.

If the north-eastern portion of America and the north western part of Europe were raised so as to get a snowy mountain range on either side of the Atlantic, sending ice-sheets down to the sea in the intervening depressed trough, and by the convergence of the axes of elevation deflecting the ocean currents and causing glaciers to creep down east and west from the mountain ranges—all the phenomena of the glacial epoch could be explained.

Reverse the process; send up Greenland and lower the North American and Scandinavian chains even to below where they now stand, bringing in again the warm currents from the South, and the post-glacial submergence takes its place. Let the Icelandic volcanic system play its part, and let there be earthquakes and jerks and oscillations, all part of the regular course of operations accompanying such movements, and we have the marine drifts all explained. The forms of life which have been driven away from the centres of ice dispersal will follow the receding glaciers back again. Observers will find in their own district evidence of land ice, or of icebergs, or of sea currents, or of glacier water, but in this less cumbrous theory there will be room for all.

The conflict of views recorded in Sir Henry Howorth's exhaustive work prepares one to believe that the matter may not be finally settled for some time, and, before public opinion comes to rest, we may expect many swings of the pendulum now far on this, now far on that side of the truth. But we welcome this protest against the extravagant views of the extreme glacialists and this valuable encyclopædia of the facts and arguments bearing on glacial phenomena which must be in the hands of every student of the subject. Our author is well known for his scientific treatment of literary subjects and for the literary skill with which he presents his scientific facts. Though he is an uncompromising advocate of what commends itself to him as the right view, he has indulged in no criticism which can be regarded as discourteous to the living or unfair to the dead.

T. MCKENNY HUGHES.

DYNAMO-ELECTRIC MACHINERY.

Original Papers on Dynamo Machinery and Allied Subjects. By J. Hopkinson, M.A., D.Sc., F.R.S. (New York: The W. J. Johnston Company, Limited. London: Whittaker and Co., 1892.)

The Dynamo. By C. C. Hawkins, M.A., A.I.E.E., and F. Wallis, A.I.E.E. (London: Whittaker and Co., 1893.)

THERE is hardly any greater authority on the subject of dynamo-electric machinery than Dr. Hopkinson. It was he who, turning his attention to the Edison machine, first showed how the iron in the magnets should be distributed, how the magnetising coils should be wound, and the machine built up so as to ensure its possessing the highest possible efficiency in every sense of the word.

This he did not attempt to do by mere theoretical speculation, though himself a great theorist, but by instituting a very complete and exhaustive set of experiments on dynamo machines under practical conditions, and graphically representing their results. No device in the whole history of the evolution of the dynamo has been of more general service than his plan of exhibiting the results of experiments in the well-named characteristic curve of the machine. This did for the dynamo what the indicator diagram had long been doing for the steam engine, though not, of course, in the same way.

With the most admirable simplicity this curve of electromotive forces as ordinates, and currents as abscissæ, gave just the information required regarding the action of the machine. Thus, when the ordinates represented the potential differences between the terminals, the inclination to the axis of abscissæ of the line joining the origin to any point gave the working resistance in the external circuit, corresponding to the current and potential difference defining the point to which the line was drawn, or, this resistance being known, gave the current and potential difference which the machine might be expected to develop with this as the working part of the circuit.

Then again, Dr. Hopkinson showed how the characteristic curve could be used to give the conditions under which an arc lamp can be made to work. It is well known that if the generating machine working on an arc lamp be run so as to give an electromotive force below a certain limiting value, the machine cannot be made to "keep" an arc. An explanation had been previously given by Dr. Siemens; but Dr. Hopkinson showed that all that was necessary was to lay down in the characteristic curve of the dynamo as already explained the line representing the *metallic* resistance R in circuit, then draw the tangent parallel to this line, and observe whether the ordinate corresponding to the normal working current of the lamp falls on the right or on the left of the point of contact. If E denote the length of the ordinate in question, and C denote the current, we have in the former case

$$dE < RdC$$

and in the latter

$$dE > RdC$$

Thus in the former case the value of dE is smaller than the increment of electromotive force required to drive the corresponding increase of current through the metallic resistance, in the latter case it is larger than this. Consequently, in the latter case, there will be an excess of electromotive force which will go to increase the length of arc. Thus the arc will continually lengthen until the current suddenly fails and the light goes out.

Hence the mere inspection of the curve settles the question as to whether the machine is running fast enough, or whether there is a sufficient margin of speed to ensure stability.

In the paper on Some Points in Electric Lighting, a large number of facts, now so well known as to have become common places of practical science, are discussed. But ten years ago, when the paper was read, many electricians engaged in supplying electric light were themselves working very much in the dark; and Dr. Hopkinson's paper was to many of them exceedingly useful as supplying facts, and especially hints as to graphical processes of investigating the behaviour of dynamos, whether used as a generator or a motor.

The next paper is that by the author and his brother, Dr. E. Hopkinson, on Dynamo-Electric Machinery, which has become justly famous as that in which the enormously useful idea of the magnetic circuit was first applied in a complete and consistent manner to the discussion of the results of experiment on different types of dynamo. In this a comparison between the characteristic curve of the machine, and the curve of magnetising force and magnetic induction, is made to give important information as to the proper disposition of the magnetic circuit, and the failure of the total induction to pass through the armature. Further, the effect of the lead of the brushes and of the current in the armature is fully discussed and graphically illustrated; and the paper closes with what were most valuable at the time, a description of the author's method of testing the efficiency of dynamos, and numerous results of experiments on machines with armatures wound according to the Hefner Alteneck plan, and the unsymmetrical horseshoe arrangement of magnets, and on others with Gramme armatures and the Siemens rectangular symmetrical arrangement of magnets. In these efficiency experiments the ingenious plan of using two similar machines in the same circuit and having their shafts coupled, one acting as generator, the other as motor, was first adopted. The motor in great measure drives the generator which feeds it, and it is only necessary to supply by means of a belt the balance of driving power required. Thus, uncertainty in dynamometric measurement of power transmitted has effect only on the estimation of this balance. The power developed by the motor can be found electrically, as likewise the electrical energy developed by the generator, and thus all the data are obtained for estimating the efficiency of the machine.

This idea has borne important fruit in the extremely valuable methods which have been invented by others for more conveniently carrying out similar dynamo experiments, and for testing transformers.

Next comes the very valuable continuation of this paper published only last year, which completes the discussion of direct current machines. In this sequel the effect on the electromotive force of the machine of the current in the armature for a given lead of the brushes is experimentally investigated, and compared with its theoretical value as given in the earlier part of the paper.

The remaining portion of the book consists mainly of papers relating to the theory of alternating currents, and the testing of alternate-current machines and transformers, and concludes with an account of the author's arrangements for applying the electric light to the lighthouses of Macquarie and Tino. The first paper on alternating currents is the one which has been so much referred to in recent discussions on the action of alternators, and the possibility of running more than one in the same circuit.

Though the increased use of alternating currents has added much to our knowledge of the behaviour and capabilities of alternators, Dr. Hopkinson's paper is, and will remain, one of the classics of the subject. But the last word of theoretical and practical explanation has not yet been said, and will probably not be said for a long time. In the meantime there is a possibility, now that the behaviour of iron in rapid magnetic cycles can be studied completely in various ways, of our obtaining further information which may clear up some of the outstanding difficulties of the subject.

Some results of a very interesting character as to rapid cycles are given in the paper on the Tests of Westinghouse Transformers. The curves showing the electromotive force and the current at different instants during a half period are plotted and come out very considerably different from the ordinarily assumed curve of series. The harmonic analysis, or the new analysing machine of Henrici and Sharpe, might with advantage be applied to them to reveal their components. From these curves the dissipation loops are plotted and made to give the loss of energy due to local currents and hysteresis in the curves.

Further description of these papers is unnecessary. They have already passed to a considerable extent into electrical literature; but a great service to practical electricians has nevertheless been done by their publication in a collected form.

In Messrs. Hawkins and Wallis's book we have little of originality; but what seems a straightforward, accurate, and fairly full account of dynamo-electric machinery. Beginning with chapters on the Magnetic Field, the Magnetic Circuit, the Production of an E. M. F., and Self-Induction, the authors enter on their main subject with a chapter on the Classification of Dynamos. The principal types of machine are described and well illustrated, so far as the number and general nature of the cuts are concerned. But while the authors have been liberal with carefully made drawings and well considered diagrams, the execution and printing of the illustrations in the text are here and there rather poor, and a higher general standard in this respect might easily have been attained.

After a general analysis, so to speak, of dynamos, in which armatures, magnets, &c., are discussed, we come to matters relating to the action of dynamos, such as series, shunt, and compound winding, and sparking and angle of lead of brushes. Then follow descriptions of typical machines, illustrated by folding sheets, and the book closes with chapters on Dynamo-Designing, and the Working and the Management of Dynamos.

We should have liked to have seen dynamo-testing worked out more fully, and a separate chapter on this important subject might easily have been given without burdening the book with matter properly belonging to works on general electrical measurements.

Considering the compass of the book—520 small 8vo pages—the authors have succeeded in placing before their readers a very great amount of valuable information, well arranged and clearly expressed, and their work will no doubt be appreciated by students and workers in practical electricity.

A. GRAY.

OUR BOOK SHELF.

Modern Microscopy: a Hand-book for Beginners. In two parts. 1. "The Microscope, and Instructions for its Use." By M. J. Cross. 2. "Microscopic Objects: how Prepared and Mounted." By Martin J. Cole. (London: Baillière, Tindall, and Cox, 1893.)

THIS book, although only extending to 104 pages, is what it professes to be, and will prove thoroughly useful to beginners. The authors understand practically their respective subjects, and this has given the capacity, never otherwise possessed, to tell the beginner accurately and efficiently what it is needful for him at the outset to know.

It is highly to be commended that they have not rendered their pages incompetent by any pretence at an introduction to the optics of the instrument, or concerned themselves with any attempt at exposition of modern optical theory. They have done what affords a more genuine evidence of their appreciation of the importance of these subjects, having presented the results of the study of them in a practical form to the beginner, so that although his earlier efforts are not complicated with mathematical demonstrations and theory, he is nevertheless taught to work, on the highest results reached through these, so far at least as they apply to his initial endeavours.

The danger of extremely elementary books on microscopy is shallowness. They have often been a mere catalogue of two or three chosen instruments, with brief accounts of the apparatus affected by the author, and descriptions of pretty or pleasing objects. The former part of this book is much more than this; it gives the results of a practical knowledge of how to employ the instrument in such a way as to attain the finest results; always remembering that it is beginners that are receiving the instruction.

There are some thoroughly sensible things said on the microscope-stand. We may differ slightly from some of these, but they are written with a knowledge of the subject, and those who follow them will not greatly err.

We can commend also the chapter on "Optical Construction." It is brief, but puts to the beginner exactly what he requires to know. The pages on "Illuminating Apparatus" are specially commendable because thoroughly experimental. In fact, the fifty-five pages devoted to modern microscopy will be a boon to every one of the many who are every year "beginning" with the use of the microscope.

But the practical character of the book is seen even more clearly in the second part of it, by Mr. Martin Cole. He at once introduces the tyro to the art of preparing and mounting his own objects. Here again it is not a mere repetition of what has been obtained from other sources that is presented, but Mr. Cole's long experience as a mounter is given to the reader unostentatiously and with pleasant and useful brevity.

There are some who, glancing at this little treatise, will at once conclude that the thirty-six pages devoted to the subject must leave it inefficiently treated even for beginners. We advise such to read the pages; and after some years of practice in most of the departments of mounting referred to and explained, we can only say that they present in a brief but a very efficient manner the facts required to enable the earliest efforts of an earnest amateur to become so successful as almost certainly to secure his interest in the subject, and cause him to intelligently pursue his pleasure and instruction, if not to aim at scientific work directed by more exhaustive treatises.

W. H. DALLINGER.

Lectures on Sanitary Law. By A. Wynter Blyth, M.R.C.S., L.S.A. (Macmillan and Co. 1893.)

THIS work presents a general view of the powers and duties of Local Authorities in relation to public health, and since the material has been compiled by one who, while he is a prominent sanitarian is also a barrister-at-law, the fact that the work is good and trustworthy, and leaves but little to be desired, goes without saying. The only point upon which there is any scope for adverse criticism is that the review of sanitary legislation appears to be, in places, a little too cursory, and in consequence some important material is a trifle too hurriedly passed over. To indicate one such instance:—There is some important material contained in the Dairies, Cowsheds, and Milkshops Orders of 1885 and 1886 which is not given, and with which the health-officer is directly concerned. Sections 10, 11, and 12 of the 1885 Order are omitted; and no one will question their right to be fully included within any serviceable abstract of the Order, since they deal specifically with certain well recognised sources of contamination, against which it is necessary to guard the milk in those places where it is stored or kept for sale.

Nothing need be more inclusive or better expressed than the majority of the work, and when in one or two places the information is a little more extended, and the statutes specially dealing with the inspection and examination of food (which are now given *in extenso* in the appendix) are incorporated in, say, another two chapters, the book will be rendered even more acceptable than it is at present to those desirous of obtaining in a readable and concise form a good knowledge of sanitary legislation.

The scope of the book embraces the entire range of public health legislation, and the volume is largely an embodiment of a series of lectures which have frequently been given by the author. The first chapter treats of the constitution of Sanitary Districts and Authorities, and includes the definitions of certain terms employed in the Sanitary Acts. Lecture ii. deals with the statutory provisions regarding nuisances; and the next three lectures are concerned with the legal aspect of sewerage and drainage, water-supply and sanitary appliances; regulations and bye-laws; port sanitary law, canal boats. Metropolitan sanitary law, the Housing of the Working Classes Act, 1890, are all dealt with in subsequent chapters; and the statutory provisions which deal with the prevention of disease are particularly well and clearly mapped out in Lectures vi. and vii. The book comprises nearly 300 well-printed pages, and it is neatly and serviceably bound.

The author must be congratulated upon having presented a rather heavy and unattractive subject in the most concise and readable form—consistent with general usefulness—of any in which it has hitherto appeared.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Royal Society.

THE article on the Royal Society, published in NATURE of June 8 by my friend Mr. Thiselton-Dyer, contains very little statement of fact to which I, or any one acquainted with the history and traditions of the Society, could wish to take exception.

It does, however, seem to me to be important to point out (a thing Mr. Thiselton Dyer has omitted to do) that the tendency of the development of the Society has been to restrict its ordinary membership to those who have done valuable work in "the improvement of natural knowledge" either by the exercise of their own mental gifts, or by assisting in some marked way—by the wise application of money or other direct influence—the efforts of others to that end. When, some thirty-five years ago, the annual number of elections of ordinary Fellows was practically restricted to fifteen by the limitation to that number of the list recommended by the Council, the chance of admission to the Society for "a member of the legislature with the keenest sympathy for science" (to quote Mr. Thiselton-Dyer's words) became small; and as the years rolled on, and the number of serious workers in science increased in unexpected proportion, it became less and less. Accordingly, not many years ago, it was determined by the Society, in order to meet this undesirable state of things, that members of the Privy Council should be eligible at any time as Fellows of the Society without reference to the annual list of fifteen prepared by the Council. Apparently the intention of this measure was to relieve the ordinary annual list of fifteen candidates for Fellowship from the presence of a certain number of members of the legislature with keen sympathy for science, and other such aspirants, and to reserve it for those for whom it could be claimed that they had done something tangible for "the improvement of natural knowledge." It seems to me that the selections made by the Council since that date confirm this view. Mr. Thiselton-Dyer makes a mistake in confounding the real services to natural knowledge rendered by Sir John Kirk, Sir George Nares, and Sir Charles Warren, with the "sympathy for science" of amiable members of Parliament.

There is another aspect of the question recently discussed which seems to me to be important. Does the Royal Society propose, or does it not, to include in its annual elections persons eminent in historical study? If it does, surely Freeman, Stubbs and Gardiner would have been Fellows of the Society. The examination and exposition of documents when they relate to an Asiatic race cannot be regarded as more akin to the investigations of the improvers of natural knowledge than is the study of the inscriptions, camps, and pottery of European peoples. Does the Royal Society explicitly or implicitly recognise claims which would give their possessor a first place in an Academy of Inscriptions or of Historical Science? I should venture to reply to this question: "Certainly not; by most definitely expressed intention such studies as those of the historian were excluded by the founders of the Society from their scope. And further, were such studies to be embraced by the Society as a new departure, it would be necessary to make special provision for them by increasing the annual number of elections, and by securing seats on the Council for one or two persons acquainted with those studies and the merits of those who pursue them."

I believe that the Royal Society is honoured and trusted by the British public as being the leading society "for the improvement of natural knowledge." Its original and deliberately chosen motto, "Nullius in verba" is a distinct profession of its purpose to appeal to experiment and the observation of phenomena, rather than to encourage the disquisitions of the bookman and compiler of history.

Though it may well be urged that such a body as "the Royal Society for the Improvement of Natural Knowledge" is wise in offering a kind of honorary membership on special terms to those who are a power in the State, there seems to be no ground for maintaining that the Fellows (as Mr. Thiselton-Dyer declares) "display themselves as reasonable, if hard-headed, men of the world" when they sacrifice one of their fifteen ordinary annual fellowships for the purpose of enrolling among their number an isolated example of the numerous body of historians and essayists who have attained some distinction in subjects and methods remote from those professedly pursued by the Society.[1]

Were the Royal Academy of Arts to assign one of its Associateships to, let us say, a distinguished botanist who is known to have a keen sympathy for Art, the world would, I venture to maintain, consider that the Academicians had not "brought themselves into touch with another field of national life," nor "displayed themselves as reasonable or hard-headed men of the world," but had simply stultified themselves whilst conferring no real honour upon their nominee. The Royal Academy includes a small number of laymen as honorary members, but it is recognised that the Academicians shall only confer their regular membership upon those of whose work they are *competent judges*, and consequently upon those who are really honoured by the selection, namely, artists.

It seems to me that *mutatis mutandis* much the same is true of the Royal Society. The Society has gained in the past, and will retain in the future, public esteem, and increasing opportunities for usefulness by aiming with singleness of purpose at "*the improvement of natural knowledge.*" To confer honour on those who have improved natural knowledge is its privilege and its duty. The appreciation of historians and of "sympathetic legislators" is a function which the Society is incapable of performing, and moreover one which few, if any, persons desire it to attempt, since it must lose dignity by assuming to adjudicate in matters in which it is incompetent.

Oxford, June 26. E. RAY LANKESTER.

ALTHOUGH my friend Prof. Lankester finds that the "tendency of the development" of the Royal Society has been to restrict the area from which its members are selected—a conclusion in which I am not disposed to agree—I do not find that he seriously impugns the account which I attempted to give of what appeared to me to be the traditional practice of the Society in the matter.

In fact in one respect he goes much further than I should myself be inclined to do in admitting as a qualification for membership "the wise application of money." I must confess that I should be disposed to regard this, for obvious reasons, with very close scrutiny.

Apart, however, from this it is evident that Prof. Lankester and those who agree with him would like to make the Royal Society much more professionally scientific (for there are very few scientific men nowadays who are not in some sort or other professional). If they succeed I am disposed to think that it would be a very much less influential body than it is at present. And I find that no inconsiderable body of the existing Fellows are of the same opinion. W. T. THISELTON-DYER.

Kew, July 1.

Ice as an Excavator of Lakes and a Transporter of Boulders.

I HAVE devoted a considerable space in a work I have recently published in which I have criticised the extreme glacial views of some writers to an issue which underlies a great deal of their reasoning, and which, it seems to me, it is absolutely necessary we should determine before we are entitled to make the deductions habitually made by them.

Before a geologist is justified in making gigantic demands upon the capacity and the power of ice as an excavator or as a distributor of erratics and other debris over level plains it is essential that he should first ascertain whether it is capable of the postulated work or not. It is not science, it is a reversion to scholasticism to invoke ice as the cause of certain phenomena unless and until we have justified the appeal by showing that it is competent to do the work demanded from it. This preliminary step is not a geological one at all. It is a question of physics, and must be determined by the same methods and the same processes as other physical questions. So far as we know the mechanical work done by ice is limited to one process. The ice of which glaciers are formed is shod with boulders and with pieces of rock which have fallen down their crevasses. These

[1] I have addressed my remarks mainly to the contentions of Mr. Dyer's article. I should wish to avoid discussing the merits of a particular election which in my opinion cannot now and never could legitimately be a subject for public comment. I wish, however, to state that I am not unacquainted with the interesting essays on the history of geological theory which we owe to the hero of that election.

pieces of rock abrade and polish and scratch the rocky bed in which they lie when they are dragged over it by the moving ice. Without this motion they can of course effect nothing either as burnishers or as excavators.

This motion has been shown by recent experiments to be very largely if not entirely a differential motion due to the viscous nature of ice, as Forbes long ago argued on *à priori* and other grounds that it was. The viscosity of ice is different at different temperatures. It differs also greatly when it is in the form of granulated ice, such as a glacier is composed of, from ice formed in a laboratory or directly frozen from water in a pond, but in any case it is slight, and it needs a considerable and a long-applied force to make it shear. The consequence is that when it rests on a level or nearly level surface, where gravity does not work, it ceases to move at all. In order that it should acquire motion sufficient to drag stones, &c., along, it is necessary that there should be some *vis a tergo*. Either the ice must rest on a slope sufficiently inclined to generate a gravitating movement in it, as a whole, or the slope of its upper surface must be sufficiently great to cause the movement of its surface layers to be continued down to and to remain effective in its nethermost parts. Every attempt made by Croll and others to invent for, and assign to, ice molecular movements capable of causing lateral motion in the stones beneath it other than those induced by gravity, seems to me to have utterly failed. The cause—the only cause which is competent to make it move is gravity acting either in one or the other way above specified.

This seems to be the inevitable conclusion whenever the problem is tested as it ought to be tested, by empirical tests. If so, it seems to put out of court the continual appeals made to ice as the distributor of debris over hundreds of miles of level plains, and as the excavator of basins and lakes at a considerable distance from mountain slopes.

In the first place, the modulus of cohesion of ice being what it is, it has been shown by Mallet, Oldham, and Irving that thrust cannot be conveyed through it for more than a short distance, since it must yield and eventually crush.

This *à priori* view is supported by the actual observation of glaciers in which we find that the rate of motion is very largely a function of the slope of the bed, and when a glacier leaves the slope on which it rests and gets on to level ground it very soon ceases to move altogether.

It has been argued that in the Ice Age the ice was piled up in dome-shaped ice sheets, and that the distribution of the boulders and the excavation of mountain lakes was due to the results of the efforts of the viscous mass to reach a state of equilibrium by hydrostatic movement, or by rolling over itself. But this ignores the very slight viscosity of ice which would require a very high slope in its upper layers to induce movement in its lower ones at all. It is impossible to see how this high slope could be secured, since the effort to restore equilibrium would be continuous, and the potential movement involved in every fresh fall of snow would at once be dissipated instead of being accumulated.

I cannot see, therefore, how under any circumstances it is possible for ice either to travel over long distances of level ground, or to excavate hollows such as the great majority of mountain lakes are.

I have not in this letter referred to the geological difficulties of such an hypothesis, which are manifold. I have limited myself to the physical difficulties alone. They seem to me to underlie the whole problem, and it is useless to discuss it until they have been solved, yet they are persistently ignored by the ardent champions of ice. That ice can do a good deal when allied with gravity is true enough, but the problem, as presented by Mr. Wallace, Prof. James Geikie and others requires that it should continue to do portentous work when no longer allied with gravity. Is it too much to ask that some justification should be offered (and nowhere better than in your catholic pages) for such an enormous unverified postulate?

Athenæum Club, July 1. HENRY H. HOWORTH.

Abnormal Weather in the Himalayas.

ON May 26 I walked from Changla Gali (about 9000 feet) to Dungar Gali (under 9000 feet) by the "pipe" road. On the way we passed (the road is cut along the side of the steep mountains) a narrow valley filled with snow to about a height of 100 feet. The width of the hard snow on the road was 20 feet. On the 28th I walked back to Changla Gali by the main road. Here we saw a great deal of snow. A bridge spanned a narrow valley, a mass of flat snow, perhaps 15 feet thick, filled the valley to the bridge. No snow ran up the valley. Then we came on two valleys converging into one at the point where the road passed. Both valleys above and the valley below were filled with snow, and the road for 150 feet was cut on the face of the snow.

In the first week of May terrific storms burst over Murree; we had constant storms at Dungar on the night of the 26th up to 12 a.m. on the day of our leaving, the 28th. On the 28th the last two miles of the road into Changla were simply carpeted with leaves and twigs broken off by a violent hailstorm. The sides of the road, sometimes the road itself (four hours after the storm), were covered with drift and massed hailstones of the size of big marbles (ice with the usual whitish centre).

This continuance of snow and this stormy weather is stated to be altogether abnormal. F. C. CONSTABLE

Changla Gali, May 29.

Peculiar Hailstones.

A FRIEND of mine writes me from Peshawar about a very curious phenomenon which I think is worth notice in your columns. The monsoon has set in this season earlier than for some years past. A few days ago in a village named Daduzai (a tehsil in the Peshawar district) rain fell, preceded by a wind storm, and with the rain came a shower of hailstones which lasted for a few minutes. The most curious part of this occurrence is that the hailstones when touched *were not at all cold*, and when put in the mouth (as is the custom in this hot country) tasted like sugar. I am further told that these hailstones were extremely fragile, and as soon as they reached the ground they broke in pieces. These pieces when examined looked like broken sticks of crystallised nitre. My informant tasted them, and was struck with their purity and sweetness. A few pieces were also sent to the Deputy Commissioner of the district. The phenomenon has been duly reported in the leading newspapers of the province, and the *Akhbar-i-Am* has noted it in its leading columns. KANHAIYALAL.

Lahore, June 20.

Crocodile's Egg with Solid Shell.

DURING the year 1885 I was stationed at Trincomalee, when it was my luck to find a large crocodile's egg near Kantalay tank. On showing the specimen to several friends who knew more about natural history than I did, they expressed their astonishment at seeing a hard-shelled egg, as the concensus of opinion was that such eggs were invariably surrounded with a soft parchment-like covering.

I made a hole in the top and bottom of the egg and blew out the contents. The shell is still in my possession, and resembles more the hard enamelled-like egg of the ostrich than anything else I have seen.

The above facts may interest those who take a pleasure in objects of natural history. J. BATTERSBY.

Murree Hills, June 7.

UNIVERSITY AND EDUCATIONAL ENDOWMENT IN AMERICA.

THE statements in the following extract are so remarkable that I think they deserve a wider publicity than they will probably receive in the pages of a Parliamentary paper.

One may hope that the reconstructed University of London will make provision for post-graduate study and the advancement of knowledge in the greatest city of the world. It must be admitted that this cannot be done without the expenditure of a good deal of money. May one hope further that the cause of the higher education will find friends amongst us in London as munificent as university and technological studies have found in one of the newest of the world's cities?

Kew, June 30.

W. T. THISELTON-DYER.

Extract from "Report for the year 1892 *on the Trade of the Consular District of Chicago." (F.O. Annual Series,* 1893, *Diplomatic and Consular Reports, No.* 1233.)

FIVE years ago the University of Chicago was not thought of, and now there are twelve fine buildings of English Gothic architecture, either finished and occupied or in course of construction, on twenty-five acres of land owned by the University in the neighbourhood of Jackson Park, near the Exhibition grounds, where three years ago was a marsh. The University has now a large staff of professors, selected from other institutions in the country and Europe, and about 1000 students. Its origin and rapid growth are greatly owing to the generosity of Mr. Rockefeller, who in 1889 offered an endowment of £120,000 if a committee could raise the sum of £80,000; this sum was quickly raised, and about the same time a merchant of Chicago presented the University with twelve acres of the ground on which the buildings now stand. Further gifts came in, and up to the present time the total donations amount to £1,284,000, of which Mr. Rockefeller alone has contributed £754,000. The sums given in 1892 amounted to £711,500, and among the gifts was the offer of a telescope, to be the largest and most powerful in the world, which, with the observatory in which it will be placed, will cost more than £150,000. The University was opened last October with a faculty of 115 professors, men and women. One of the features of its regular work will be university extension and a system for the education of the masses.

A magnificent gift was last year presented to the city, and entitled the Armour Institute, after the patriotic and public benefactor of that name. It consists of a large and handsome building already completed, and fitted interiorly with marble wainscoting on every floor, marble arches and marble bath rooms, and the gift was accompanied with an endowment of £289,000. It is to be used as a manual training school and an institute for every branch of science and art; it is fitted with laboratories, forges, gymnasium, and library, and contains electrical, lecture, and other rooms for domestic sciences. It is intended as a benefit to young men and women of every class to be within the range of the poorest, and is taking the form of a school of technology.

ANTIPODEAN RETRENCHMENT.

LAST week a brief reference was made in these columns to the decrease in the grant to the University of Melbourne—a curtailment only justifiable under very special circumstances, and one that may bring reproach on the Colony that adopts it. Since then we have seen a letter in the *Journal of Education* for July by Dr. E. A. Abbott, late Headmaster of the City of London School. The letter is as follows:—

I venture to ask space for the following extract from a letter I received to-day from the Professor of Mathematics in Auckland College, New Zealand. Prof. W. S. Aldis was Senior Wrangler and First Smith's Prizeman in 1861, and subsequently, for several years, Principal of the College of Physical Science in Newcastle-on-Tyne. The failure of his wife's health induced him, about ten years ago, to accept the Auckland Professorship, at some sacrifice of income, on the understanding, of course, that he was irremovable as long as he could do the work. After nearly ten years of service, here is the result, as stated in the extract, which bears date May 19. I give it with the mere suppression of the name of the chief mover in this business.

> "Last Monday —— succeeded in getting a majority of the Council to give me six months' notice of the termination of my engagement, on the ground that the amount of work I did could be perfectly well performed by plenty of men who could be got for a much lower salary. . . . No charge of incompetence or neglect of duty has been made against me, unless by slander behind my back. I have never been asked to meet the Council; the debates were held with closed doors; and, before I even knew what was being proposed, I was allowed to read the result of their discussion in the *New Zealand Herald*."

Those who know my old schoolfellow, Prof. Aldis, as a man incapable of dereliction of duty or exaggeration of fact, will think that the only way of meeting the necessities of the case is to rescind the resolution. Others may reasonably defer their final judgment till they hear what is to be said on the other side; but meantime I would appeal to all University men to defer applying for the professorship. For the present, to succeed a professor thus arbitrarily dismissed by the Council involves not only the possibility of being similarly treated, but also the certainty of contributing to what Sir Robert Stout has justly described as "a grievous injury to higher education." Many teachers, and many University men who are not teachers, will, perhaps go with me still further, and agree that, if Prof. Aldis's statements cannot be denied, no one can take the post without some forfeiture of self-respect.

Dr. Abbott puts the case plainly and fairly enough, and, lacking an explanation from the Council concerned, we conclude that this is another example of the reactionary policy of retrenchment which now fills the minds and dictates the deeds of Colonial officials. Let them retrench by all means, but in the right direction. There could hardly be a more short-sighted and mistaken policy than that of curtailing educational grants in order to redeem a position lost by extravagant expenditure. Wealth-producing power and facilities for obtaining knowledge go hand in hand. In the past many of the Colonies have proved that they recognised the prime importance of their Universities and similar establishments. Indeed, they have often shown the way to the authorities at home. Apparently, however, this wisdom is departing from Colonial Councils, for healthy branches are being lopped off indiscriminately, while obtrusive suckers at the roots of the constitution are left untouched. However, it is not too late to rescind the measures that have been taken—measures that are derogatory both to the good sense and dignity of Colonial Governments. We trust that the next mail will bring us news of the reinstatement of Prof. Aldis and the restoration of University grants.

SCIENCE IN THE MAGAZINES.

THE July magazines contain a few papers of scientific interest. In the *New Review* Mr. E. R. Spearman writes on "Criminals and their Detection." This article is a vigorous protest against the crude methods of identification employed at Scotland Yard. In spite of the thousands of blunders that have been made, our police authorities are stolidly indifferent to their imperfections, and look upon the Bertillon system as a "scientific fad." But this is the way in which the official mind usually views matters of scientific importance. To show the absurdity of the position taken up, Mr. Spearman gives a full description of the Bertillon process o measurement, with the results obtained since the method was adopted in France, and compares it with the haphazard system of identification used in our prisons. But for the fact that officialism never acknowledges itself to be in the wrong, *bertillonage* would have been established in England long ago.

The Bertillon system, says Mr. Spearman, is fast circling the globe. Our great Indian Empire has taken it up, the whole province of Bengal being recently put under its protection, and still more recently the island of Ceylon. Even in still more Eastern Asia, Japan has borrowed M. Bertillon's scheme. In Eastern Europe, Russia (St. Petersburg and Moscow) and Roumania are using the system, which is also practised in Norway and Switzerland. In North America the United States Government has successfully applied anthropometry to deal with deserters in the army and navy; while Chicago not only uses the system for its own purposes, but is the centre of a large field of operations in the States and in the adjoining portions of the Dominion of Canada. Beside this, on the Pacific coast it was successfully used to enforce the Chinese immigration law, the Celestials being able to use each other's permits with impunity, all being alike as two peas to the casual Caucasian glance, but not to the Bertillon compasses. In South America the Bertillon system has also penetrated, the Argentine Confederation making use of it.

The anthropometric system could be established in England at the present time, for Mr. Spearman points out that in the Penal Servitude Act, 1891, it is enacted that

The Secretary of State shall make regulations as to the measuring and photographing of all prisoners who may for the time being be confined in any prison, and all the provisions of section six of the Prevention of Crimes Act, 1871, with respect to the photographing of prisoners, shall apply to any regulations as to measuring made in pursuance of the section.

Dr. S. S. Sprigge has an article on "The Poisoning of the Future." He says:—

There are two directions which the poisoner of the future may take in an intelligent attempt to use superior knowledge in the accomplishment of undetected crime. One of them is the bringing of the older methods of poisoning to perfection by the exhibition of subtler drugs. The other, and by far the more terrifying, is the employment by the poisoner of the results of recent biological research.

Neither of these methods is likely to be very successful, for those who understand the power of such deadly essences as strychnine, atropine, digitalin, and aconitine, or know how to isolate, cultivate, preserve, and inoculate the germs of a malignant disease, will be comparatively marked men, inasmuch as they will belong to a limited class.

The *Humanitarian* appears this month for the first time as a magazine. In it M. A. Bertillon gives a description of the anthropometrical measurements made in France under his direction. The measures taken are (1) height, (2) length of head, (3) maximum breadth of head, (4) length of middle finger of left hand, (5) maximum length of left foot, (6) maximum length of arms extended, (7) colour of the eyes. M. Bertillon describes in detail all the operations, and shows how the measures are classified so that the question as to whether a prisoner has been arrested before or not can be irrevocably settled in a few minutes.

In the *Contemporary Review* Mr. G. J. Romanes, F.R.S., furnishes a postscript to his article in the April number in support of Weismannism against Mr. Herbert Spencer. The points touched upon are (1) the principle of Panmixia, or cessation of selection; and (2) the influence of a previous sire on the progeny of a subsequent one by the same dam. Mr. Spencer briefly replies to Prof. Romanes, and Prof. Marcus Hartog follows with a short description of the works of Weismann, from the publication of the essay on "Heredity" in 1883 to the last conception of the germ-plasm and the theory of variation at present held by the great zoologist of Freiburg.

Prof. Thorpe, F.R.S., contributes to the *Fortnightly Review* a descriptive account of the recent solar eclipse in the form of a reprint of a discourse delivered at the Royal Institution. As the article contains no information of scientific moment that has not been chronicled in these columns, further comment upon it is unnecessary.

The *Century Magazine* contains an article by Dr. Allan McLane Hamilton on "Mental Medicine," or the treatment of disease by suggestion. Though a vast amount of quackery is carried on in connection with hypnotism and mesmerism, there is no doubt that many cases have been successfully treated.

It is only within the past few years that scientific men have really adopted suggestion in a rational way, and the advances in phychology and psychopathology have paved the way for the use of a most potent agent. Our knowledge of disorders of motility and the disturbance of the governing coordinating faculties permits us to determine the pathology of certain convulsive and spasmodic conditions, which until recently were simply looked upon as vague symptomatic states. Writer's cramp, which is a diseased automatism, has been repeatedly cured by suggestion made during the hypnotic state. I have seen forms of persistent tremor, chorea, speech defects, and other motor disturbances very much ameliorated, if not always cured, by the methods of Luys and Bernheim. In England and elsewhere suggestion has been used for the correction of certain mental states manifested in moral perversion, among which dipsomania and certain varieties of infantile viciousness figure; and my own experience has convinced me that in some insanities it is certainly a most valuable means for combating the development of delusions, and in restoring the equilibrium of an unbalanced nervous system.

"The Galaxy" (seen through a telescope) forms the subject of a short poem by Mr. Charles J. O'Malley. He finely describes the Milky Way in the lines—

"Luminous archipelago of heaven!
Islands of splendour sown in depths of night."

In *McClure's Magazine* Dr. H. R. Mill describes the Arctic Expeditions of Nansen and Jackson under the title "The Race to the North Pole." The former expedition started from Christiania a few days ago, but Mr. Jackson will not leave England with his companions until about the middle of July, or perhaps the beginning of August. He intends to approach Franz-Josef Land, which will be a comparatively easy task, and then to advance over the ice in sledges, trusting that the land-ice stretches northwards to the immediate neighbourhood of the Pole. If, however, Franz Josef Land proves not to have a great northerly extent, an advance may be made on the sea-ice, carrying boats for crossing open water. Mr. C. Moffett summarises the programme of Lieut. Peary's expedition, pointing out several important considerations which make it probable that the expedition will attain a considerable measure of success. It remains to be seen whether any or all the explorers will reach the goal. The race is a long one, and will tax to the utmost the energies and pertinacity of those who have elected to run.

"An Expedition to the North Magnetic Pole" is the theme of an article by Colonel W. H. Gilder. About three years ago Prof. Mendenhall wrote to the Secretary of the United States Treasury as follows:—

"The importance of a redetermination of the geographical position of the North Magnetic Pole has long been recognised by all interested in the theory of the earth's magnetism or its application. The point as determined by Ross in the early part of this century was not located with that degree of accuracy which modern science demands and permits, and, besides, it is altogether likely that its position is not a fixed one. Our knowledge of the secular variation of the magnetic needle would be better increased by better information concerning the Magnetic Pole, and, in my judgment, it would be the duty of the Government to offer all possible encouragement to any suitably organised exploring expedition which might undertake to seek for this information."

Acting upon a further recommendation, the Secretary of the Treasury requested the President of the National Academy of Sciences to appoint a committee of its members "to formulate a plan or scheme for the carrying out of a systematic search for the North Magnetic Pole and kindred work," and such a committee was subsequently appointed, with Prof. S. P. Langley, Secretary of the Smithsonian Institution, as Chairman.

The observers will be selected from among the officers of the United States Navy attached to the Coast Survey, who have had special training in magnetic field work, and a scheme of the observations to be made has been drawn up by Prof. C. A. Schott.

It is proposed to charter a steam whaler to take the party from St. John's, Newfoundland, to the northern part of Repulse Bay, which, being directly connected with Hudson's Bay, is the nearest point to the Pole, containing area that is accessible any year. There a permanent station is to be erected, where regular observations will be continued all the time, and from which each spring a field party (perhaps two) will start to locate the geographical position of the Pole.

NOTES.

THE annual meeting of the Institution of Naval Architects commenced at Cardiff on Tuesday, when an important paper upon "Fast Ocean Steamships" was read by Dr. Elgar. Owing to the rough weather, Lord Brassey, the president, was unable to be present, his yacht being prevented from reaching the fort.

THE forty-second meeting of the American Association for the Advancement of Science will be held during August at Madison, Wisconsin. The local secretary is Prof. C. R. Barnes, of the State University.

THE second annual meeting of the International Union of Photography will be held in Geneva from August 21 to 26. The headquarters of the Union are at 33, Rue Rembrandt, Antwerp.

ARRANGEMENTS have been made for a visit of the Geologists' Association to Ireland from July 24 to 29. The directors of the excursion are Profs. W. J. Sollas, F.R.S., and Grenville A. J. Cole, and a very attractive programme has been provided. In addition to the serious work, more than one social gathering is promised, so the trip will doubtless be enjoyed by all who undertake it. A geological map of the district to be visited, prepared by Prof. Cole, is printed in the special circular issued for the excursion by the Association, and Prof. Sollas's paper on the geology of Dublin and its neighbourhood, read before the Association on the 7th inst., is now in the press, and will be published the day before the party leaves London. As it is important to obtain an early estimate of the probable number of the party, all members who propose joining the excursion should apply at once to the Secretary, Mr. Thos. Leighton, Lindisfarne, St. Julian's Farm Road, West Norwood, S.E.

A COPY of the report of the Zoological Society that has just been printed has been received. Its contents will be summarised next week.

THE fifth Congress of Archæological Societies in union with the Society of Antiquaries was held on Tuesday at Burlington House, Sir John Evans, K.C.B., F.R.S., being in the chair. About forty delegates were present, including Lord Hawkesbury, Mr. Stanley Leighton, M.P., Profs. Flinders Petrie, and E. C. Clark, &c. It was announced that progress had been made with the archæological maps of Essex, Derbyshire, Sussex, and Surrey. Several papers were read, one on "A Photographic Record of Archæological Objects" exciting an interesting discussion.

THE Laboratory of the Marine Biological Association at Plymouth has still a few tables unoccupied for the summer vacation. Applications for permission to work there should be sent in without delay to the Director.

WRITING from Murree, on June 7, Mr. F. C. Constable says that, during a recent hailstorm, corrugated iron roofs were in many cases perforated by the hail. He measured one hailstone four hours after the storm, and found it to be 4½ inches round.

A VIOLENT thunderstorm occurred on Ben Nevis last week from 11 p.m. of Friday to 2 a.m. of Saturday, St. Elmo's fire appearing there at the same time. During another thunderstorm on Saturday afternoon flashes came off from the telegraph wire connections inside the observatory; and about the same time a fire-ball was seen to strike the ground near the foot of the hill. The hygrometric fluctuations at the time were remarkable.

DURING the past week sharp thunderstorms have occurred in many parts of the British Islands, accompanied by hail and very heavy rain. Between the 7th and 9th the fall within twenty-four hours exceeded an inch at several places in the north of England and in parts of Scotland, and in the north of Ireland on Sunday it amounted to 2·81 inches, a fall more than double the total for the month of June this year. The temperature was also exceptionally high in the southern parts of England during the first part of the period, the maximum reading being 89°·9 at Greenwich on Friday and Saturday, a temperature which was not equalled in any part of the summer during the five years 1888–92, and at Cambridge the shade reading on Saturday registered 92°.

SINCE February, 1892, a Richard thermograph has been installed on the summit of the Obir, at a height of 2140m., or about 1000m. below the level of the Sonnblick Observatory. The records of temperature up to February, 1893, as shown by this thermograph, were communicated and discussed by Director J. Hann at a recent meeting of the Vienna Academy (June 12). They afford a valuable contribution to the knowledge of the daily changes of temperature in the higher regions of the atmosphere. A comparison with the corresponding temperatures registered on the Sonnblick shows an almost identical course of changes, except that in summer the range on the Obir was perceptibly larger. During eight months, from October to May, hardly any daily variation is recorded in the decrease of temperature with height between the Obir and Sonnblick. In the summer months, the most rapid decrease was found to occur at 1 p.m., being 0°·74 per 100m., the least rapid at 11 p.m., being 0°·61 per 100m. The mean decrease per 100m. for the summer months was 0°·67, for winter 0°·54, and for spring and autumn 0°·56.

A NEW determination of the mass and the density of the earth has been made by M. Alphonse Berget, who describes his method in the current number of the *Comptes Rendus*. It consisted in altering the level of a lake by 1 m., and noticing the effect produced upon a hydrogen gravimeter such as was used by Boussingault and Mascart to determine the diurnal variation of gravity. The lake was that of Habaz-la-Neuve, in Luxemburg, of 79 acres area, belonging to M. François de Curel. The level could be raised or lowered in a few hours. The variation of the column of mercury was minutely observed by means of Fizeau's interference fringes, produced *in vacuo* between the surface of the mercury and a piece of plane-polished glass at the bottom of the observing tube. Two series of readings were taken, the one on lowering the level of the lake by 50 cm. and 1 m., the other on raising it by the two corresponding amounts. The displacement of the column for a change of level of 1 m. was $1·26 \times 10^{-8}$ cm. The value for K, [the constant of gravitation, *i.e.* the attraction in dynes produced by a mass of 1 gr. upon another placed 1 cm. from it in air, was found to be $6·80 \times 10^{-8}$. The mass of the earth was found to be $5·85 \times 10^{27}$ grammes, and its density 5·41, which is in fair agreement with results hitherto obtained.

DURING the cruise of the *Manche* in the neighbourhood of Jan Mayen and Spitzbergen, M. G. Pouchet made some interesting observations of the various kinds of ice to be found on those barren Arctic islands. In the northern lagoon of Jan Mayen, which was partly covered with ice on July 27, the ice, according to a description in the *Comptes Rendus*, was formed of irregular vertical prisms about 10 mm. thick separated by spaces of about 1 mm. and joined at the upper surface by a uniform layer of semi-transparent ice 1 to 2 mm. thick. At

Research Bay, Spitzbergen, the gigantic front of the two glaciers which flow into the sea presented three different tints. At the base some parts were quite dark, suggesting deep caves, but really consisting of pure homogeneous, compact ice. The middle region was greenish-blue, and the upper, consisting of snow-ice, was white. The ice-floes were either white or greenish-blue, or of an extremely intense emerald green. On taking one of the latter out of the water it was found to consist of homogeneous limpid ice, absolutely colourless to the thickness of 1 m. or so. The deep green colour was due to its illumination by the green water of the bay, which, like that of the Isfjord, is of an intensely green colour.

AN important paper by Messrs. Sarasin and De la Rive is published in the *Archives des Sciences Physique et Naturelles* and contains an account of a series of experiments on the interference of electrical waves after reflection from a metallic screen. The authors being of opinion that the results obtained by Hertz and themselves in a former investigation were vitiated on account of the reflecting surface being too small, undertook this series of experiments, using as a reflecting surface a sheet of zinc 16 metres long and 8 metres high. The arrangement employed was almost the same as that used by Hertz, the spark-gap of the oscillator, however, being surrounded by oil. The resonators were circular, and had been used in a previous series of experiments on the propagation of electrical waves along conducting wires, in which it had been found that each resonator responds to waves of a definite wave-length, and to these only. A series of observations, made with a view of ascertaining the minimum size of mirror, which gives consistent results with resonators of different sizes, showed that for a resonator of 75 cm. in diameter the reflecting surface must have a length of from 12 m. to 14 m. and a height of 8 m., while for a resonator of 35 cm. in diameter a mirror 5 m. long and 3 m. high is sufficient. The results obtained may be summed up as follows:—(1) A circular resonator has a constant wave-length to which it responds, whatever be the dimensions of the oscillator, the strength of the induced spark only varies, attaining a maximum value for a certain length of the oscillator, which gives waves in unison with the resonator. (2) The quarter wave length of a circular resonator is approximately equal to twice its diameter. (3) In the case of normal reflection from a metallic mirror the first node coincides exactly with the surface of the mirror. (4) The velocity of propagation of the electrical waves is the same in air as along conducting wires.

WE have received a copy of a calibration curve of one of Prof. Perry's new electric current meters, which are now being constructed for practical work by Messrs. Johnson and Phillips. This meter, as some of our readers may know, consists of a copper bell (with open neck) which rotates about its axis in a radial magnetic field formed between an inner cylinder and an outer surrounding cylinder, both of iron, and magnetised by a coil surrounding the inner. As the surfaces of these cylinders are furnished with teeth projecting towards one another, leaving just sufficient clearance space for the bell, there are, alternating with one another round the bell, places of maximum and minimum field intensity. The bell is immersed in mercury, and being covered with varnish, except at the lip and at the neck, where it receives and gives out current, is the seat of a current sheet running from the lip to the neck. Thus the bell rotates about its axis with a speed depending on the current flowing and the intensity of the magnetic field. By the ingenious device of rendering the field non-uniform, the resisting couple due to solid and fluid friction is made small in comparison with that due to Foucault currents; and as the latter is proportional to the square of the maximum field intensity multiplied by the speed of rotation, and the driving couple to the product of the field intensity and the current, a working formula is obtained in which the current is proportional to speed and to field intensity. By making the field sufficiently intense, the speed can be made as slow as may be desired, and error from neglect of friction proportionately diminished. The meter is thus very simple, and unlikely to get out of order, or to be inconstant or untrustworthy in action. It is claimed, further, that the temperature errors balance one another, and this is borne out by the fact that the calibration curve is a straight line from the first current marked, 2·5 ampères, to the highest, 60 ampères. The instrument must therefore, within the range of currents for which it is designed, work with great accuracy.

THE *Philosophical Magazine* for July contains a note by Messrs. Harvey and Hird on some differences they have observed in the behaviour of positive and negative electricity in high frequency discharges. They find that, when a brush discharge takes place in air between a point and a plate, the plate is always positively charged, although the discharge is oscillatory. In the case of hydrogen, however, the plate becomes negatively electrified. Thus in the case of a brush discharge in air or oxygen the positive electricity passes more readily than negative from a point into any neighbouring conductor, while in hydrogen the reverse takes place, negative electricity passing more readily.

WEBER showed some years ago that the eggs of the common pike could be caused to produce double monstrosities if the recently fertilised ova were violently shaken. Mr. John A. Ryder has recently communicated a paper to the Academy of Natural Sciences of Philadelphia, which leads to the belief that the Japanese produced their singular breeds of double-tailed goldfishes by taking the eggs of the normal species of goldfishes and shaking them, or disturbing them in some way, as Prof. Weber did with the eggs of the pike. They would thus obtain some complete double monsters, some with two heads and a single tail, and some with double tails. Those most likely to survive would be those with only a duplication of the tail. These being selected and bred would probably hand down the tendency to reproduce the double tail, a tendency which could become fixed and characteristic if judicious selection were maintained. Mr. Ryder thinks that his investigation warrants the conclusion that the regenerative power of organisms disappears as we rise in the scale of organisation, last of all in the peripheral extremital parts. He further observes that the power to produce monstrosities or cogenital aberrations of development due to external disturbances of segmentation, during growth, diminishes in the higher forms *pari passu* with the advance in development.

IN a number of papers communicated to the American Philosophical Society, the American Academy of Arts and Sciences, and the Boston Society of Natural History, Mr. A. S. Packard gives the results of studies on the life-history of some Bombycine moths. He has worked out the transformations of several of the lower Bombyces, and has arrived at some valuable results. He has treated the larvæ as though they were adult, independent animals, and has worked out their specific and generic as well as family characters. The origin of mimetic and protective characters has been traced, and the time of larval life when they are assumed ascertained. This involves a study of the development of the more specialised setae, spines, tubercles, lines, spots, and other markings. Facts have also been obtained with regard to the ontogeny of American species and genera, which, when compared with the life-histories of European, Asiatic, and South American Bombyces, may lead to a partial comprehension of the phylogeny of the higher Lepidoptera.

THE *Essex Naturalist*, No. 4, contains an address on periodicity in organic life, delivered by Mr. Henry Laver as retiring President of the Essex Field Club. Reasons are given for the belief that plant and animal life periodically fluctuate in richness and scarcity.

AT Trenton, and the Delaware Valley, and Ohio, flints have been found in ice-age drift and described as implements of palæolithic man. In three papers received from Mr. W. H. Holmes this interpretation is disputed, and the "finds" are said to be of Indian manufacture—a view which, if accepted, tells against the existence of glacial man in America.

PROFS. L. CICCONE and F. CAMPANILE have prepared a set of tables showing the intensity of gravity, in C.G.S. units, for every ten minutes of latitude (*Rivista Scientifico-Industriale*). They also give the value of *g* at all the principal observing stations in the world.

OWING to the delay in the publication, by the U.S. National Museum, of a "Monograph of the North American Bats," by Dr. Harrison Allen, the introduction to the Bulletin has been issued in advance. Judging from it, the coming memoir will be of an important character.

MESSRS. FRIEDLANDER AND SON, Berlin, have issued their *Natural History News*, No. 10.

THE "Transactions of the Leicester Literary and Philosophical Society," vol. ii., part 12, contains a paper on stings and poison fangs, by Mr. G. T. Mott, and a number of notes on some East Anglian birds, by Mr. L. Creaghe-Haward.

A VOLUME has just been published containing the results of rain, river, and evaporation observations made in New South Wales during 1891, under the direction of Mr. H. C. Russell, C.M.G., F.R.S., the Government Astronomer of the colony.

IN *Das Wetter* for May G. Falkenhorst gives an account of the various plants which are affected by weather, including the paternoster-pea (*Abrus precatorius*), or "weather plant," the claims of which as a prognosticator of coming weather were shown to be groundless in the *Kew Bulletin* of January 1890. He points out that the indications of these hygroscopic plants, however worthy of study from a botanical point of view, only refer to simultaneous changes of weather.

THE Royal University of Ireland has issued its calendar for the year 1892. The papers set at the examination held during the year are published in a separate volume as a supplement to the calendar.

THE "Matriculation Directory" has been published by the University Correspondence College Press. It contains solutions to the questions set at the matriculation examination of London University last month, and articles on the special subjects for January and June next year.

"DIE MEDICINISCHE ELECTROTECKNIK," by Dr. J. L. Hoorweg, is a little book, dealing chiefly with elementary facts and principles more or less connected with medical electricity. Magnetism, statical electricity, voltaic electricity, and electrical measurements are the subjects of four separate chapters, and the remaining three chapters are devoted to a study of the action of electricity upon the human body, electro-medical apparatus, and various methods of electrification. The text is illustrated by seventy-seven figures and diagrams.

THE second number of Alembic Club Reprints can now be obtained from Messrs. Simpkin, Marshall and Co. It is entitled "Foundations of the Atomic Theory," and contains reprints of papers by Dalton and Wollaston, and an extract from Dr. Thomas Thomson's "System of Chemistry," in which book the earliest printed account of Dalton's views was given.

A NEW acid containing chromium and sulphuric acid, possessing somewhat remarkable properties, is described by M. Recoura in the current number of the *Comptes Rendus*. It is related to pyrosulphuric acid, $H_2S_2O_7$, in a manner somewhat similar to that in which the chromosulphuric acid, $(SO_4)_2Cr_2(SO_4H)_2$, previously prepared by M. Recoura, is related to ordinary sulphuric acid. Its constitution is represented by the formula $(S_2O_7H)_4Cr_2(OH)_2$. Its most remarkable property is that the two atoms of hydroxylic hydrogen are readily replaceable by metals to form salts, the whole of which, even those yielded by the introduction of the metals of the alkalies and of ammonium, are completely insoluble in water, although the acid itself is readily soluble. It has been termed chromopyrosulphuric acid. In order to prepare it a solution containing one molecular equivalent of chromic sulphate, $Cr_2(SO_4)_3$, and five molecular equivalents of sulphuric acid is evaporated over a water-bath, when a syrupy liquid of a deep green colour is eventually obtained. This liquid is then further heated to a temperature of 110–115° for a couple of days, which treatment induces a complete change of character and transparent tabular crystals of the new acid, possessing a vitreous lustre and a bottle-green colour, are deposited. Its formation is represented by the following equation:—

$$Cr_2(SO_4)_3 + 5H_2SO_4 = (S_2O_7H)_4Cr_2(OH)_2 + 2H_2O.$$

THE properties of chromopyrosulphuric acid differ widely from those of chromosulphuric acid. It is readily soluble in water, forming an opaline yellowish-green solution. This solution yields precipitates with the solutions of all commonly occurring salts, those of the alkalies not excepted. It may be generally stated that upon the addition of the solution of any metallic salt whatever to a solution of chromopyrosulphuric acid, a flocculent precipitate, more or less green in colour, is obtained. The precipitate, however, is not chromopyrosulphuric acid in which merely the hydroxylic hydrogen is replaced by the metal of the salt employed. One half of the pyrosulphuric acid is detached, and in contact with the water present produces four molecules of free ordinary sulphuric acid. The salt precipitated is thus derived from the acid $(S_2O_7)_2Cr_2(OH)_2$. For instance, when a solution of potassium chloride is added to a solution of chromopyrosulphuric acid the following change occurs:—

$$(S_2O_7H)_4Cr_2(OH)_2 + 2KCl + 2H_2O = (S_2O_7)_2Cr_2(OK)_2 + 2HCl + 4H_2SO_4.$$

Similarly copper sulphate solution produces a pale green precipitate of the salt $(S_2O_7)_2Cr_2{<}^{O}_{O}{>}Cu$.

Solutions of caustic alkalies act like salts. Thus, when a solution of caustic soda of known strength is slowly added a precipitate of the sodium salt $(S_2O_7)_2Cr_2(ONa)_2$ is thrown down, and the solution attains its neutral point when ten molecular equivalents of soda have been added, the amount required to form the above salt and to neutralise the four molecules of sulphuric acid liberated. M. Recoura has also isolated the acid itself from which these salts are derived, and promises a description of its properties in a subsequent memoir.

NOTES from the Marine Biological Station, Plymouth.—Last week's captures include the Nemertines *Prosorhochmus Claparedii* and *Carinella linearis*, numbers of the Polychæte *Myzostomum* on *Antedon rosacea*, various species of the Pantopod genera *Phoxichilus*, *Nymphon* and *Ammothea*, the Isopod *Apseudes talpa*, the Schizopod *Heteromysis formosa*, the Brachyuran *Achæus Cranchii*, and the Nudibranchiate Mollusca *Æolidiella glauca* and *Galvina cingulata*. The chains of the

Salp *Thalia democratica-mucronata* have now for the most part broken up, and the detached sexual forms, each with a contained embryo, have been taken in considerable numbers. The floating fauna has also included Cirripede and Copepod Nauplii, Polychæte trochospheres and Molluscan veligers. Among Leptomedusæ *Clytia Johnstoni* and small *Obeliæ* have been abundant; and among Anthomedusæ *Sarsia eximia* has been observed, together with numbers of an apparently undescribed species of *Dysmorphosa*, resembling *Rathkea octopunctata* in its power of budding from the manubrium. The Mollusc *Galvina cingulata* and the Tunicate *Thalia democratica-mucronata* are now breeding.

THE additions to the Zoological Society's Gardens during the past week include an American Black Bear (*Ursus americanus*) from Canada, presented by Mr. Joseph Politzer; a Hawk's-billed Turtle (*Chelone imbricata*) from the West Indies, presented by Mr. C. Melhado; two Common Buzzards (*Buteo vulgaris*) European, deposited; two Australian Crows (*Corvus australis*) from Australia, purchased; a Thar (*Capra jemlaica*, ♀), a Triangular-spotted Pigeon (*Columba guinea*), a Cardinal Grosbeak (*Cardinalis virginianus*), two Hybrid Pied Wagtails (between *Motacilla lugubris*, ♂, and *M. melanope*, ♀) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

A NEW COMET.—A telegram received from Prof. Krueger announces that a comet with a bright tail was discovered by M. Quenisset at M. Flammarion's observatory, Juvisy, on July 9, its approximate place being R.A. 7h. 50m., N. Decl. 48° 10′. The comet is therefore in the constellation Lynx.
